CRUCIAL PARAMETERS IN SELECTING A NEUROMUSCULAR BLOCKING AGENT

	Norcuron® (vecuronium bromide) for injection	Atracurium besylate
HEMODYNAMICS	No significant variations in blood pressure, cardiac output, or systemic vascular resistance.[1]	Statistically significant variations in blood pressure, cardiac output, and systemic vascular resistance.[1] ($P<.05$)
HISTAMINE	Available clinical experience indicates that reactions commonly associated with histamine release are unlikely to occur.[1-4]	Precautions advised for patients in whom substantial histamine release would be hazardous (eg, clinically significant cardiovascular disease, asthma).[5]
RECOVERY To 25% of control To 95% of control	 25-40 min[3] 45-65 min[3]	 35-45 min[5] 60-70 min[5]
DOSING FLEXIBILITY	The initial recommended dose is 0.08-0.1 mg/kg. Dose can be increased up to 0.28 mg/kg for long cases without significant histamine release or related cardiovascular side effects.[1,3,4]	Initial recommended dose is 0.4-0.5 mg/kg. A moderate histamine release and significant falls in blood pressure have been seen following a dose of 0.5 mg/kg ($P<.05$) and 0.6 mg/kg.[*2,5,6]
STORAGE & SHELF LIFE	2-year shelf life in lyophilized form at room temperature.† Can be reconstituted with various IV solutions including Lactated Ringers.‡	2-year shelf life under constant refrigeration.† Upon removal from refrigeration to room temperature storage, use within 14 days even if rerefrigerated.[5]

* Dose of atracurium above 0.5 mg/kg is not recommended.
† As originally supplied by the respective manufacturers.
‡ Storage after reconstitution varies with solution. See package insert.

Norcuron®

Norcuron®

(vecuronium bromide) for injection

Before prescribing, please consult complete product information, a summary of which follows:

THIS DRUG SHOULD BE ADMINISTERED BY ADEQUATELY TRAINED INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS, AND HAZARDS.

CONTRAINDICATIONS: Norcuron® is contraindicated in patients known to have a hypersensitivity to it.

WARNINGS: NORCURON® SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH ITS ACTIONS AND THE POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND REVERSAL AGENTS ARE IMMEDIATELY AVAILABLE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR CONTROL RESPIRATION. TO REDUCE THE POSSIBILITY OF PROLONGED NEUROMUSCULAR BLOCKADE AND OTHER POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING LONG-TERM USE IN THE ICU, NORCURON® OR ANY OTHER NEUROMUSCULAR BLOCKING AGENT SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSES BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH ITS ACTIONS AND WHO ARE FAMILIAR WITH APPROPRIATE PERIPHERAL NERVE STIMULATOR MUSCLE MONITORING TECHNIQUES (see PRECAUTIONS). In patients who are known to have myasthenia gravis or the myasthenic (Eaton-Lambert) syndrome, small doses of Norcuron® may have profound effects. In such patients, a peripheral nerve stimulator and use of a small test dose may be of value in monitoring the response to administration of muscle relaxants.

PRECAUTIONS:

Renal Failure: Norcuron® is well tolerated without clinically significant prolongation of neuromuscular blocking effect in patients with renal failure who have been optimally prepared for surgery by dialysis. Under emergency conditions in anephric patients some prolongation of neuromuscular blockage may occur; therefore, if anephric patients cannot be prepared for non-elective surgery, a lower initial dose of Norcuron® should be considered.

Altered Circulation Time: Conditions associated with slower circulation time in cardiovascular disease, old age, edematous states resulting in increased volume of distribution may contribute to a delay in onset time, therefore dosage should not be increased.

Hepatic Disease: Limited experience in patients with cirrhosis or cholestasis has revealed prolonged recovery time in keeping with the role the liver plays in Norcuron® metabolism and excretion. Data currently available do not permit dosage recommendations in patients with impaired liver function.

Long-term Use in I.C.U.: In the intensive care unit, in rare cases, long-term use of neuromuscular blocking drugs to facilitate mechanical ventilation may be associated with prolonged paralysis and/or skeletal muscle weakness that may be first noted during attempts to wean such patients from the ventilator. Typically, such patients receive other drugs such as broad spectrum antibiotics, narcotics and/or steroids and may have electrolyte imbalance and diseases which lead to electrolyte imbalance, hypoxic episodes of varying duration, acid-base imbalance and extreme debilitation, any of which may enhance the actions of a neuromuscular blocking agent. Additionally, patients immobilized for extended periods frequently develop symptoms consistent with disuse muscle atrophy. The recovery picture may vary from regaining movement and strength in all muscles to initial recovery of movement of the facial and small muscles of the extremities then to the remaining muscles. In rare cases recovery may be over an extended period of time and may even, on occasion, involve rehabilitation. Therefore, when there is a need for long-term mechanical ventilation, the benefits-to-risk ratio of neuromuscular blockade must be considered. Continuous infusion or intermittent bolus dosing to support mechanical ventilation has not been studied sufficiently to support dosage recommendations.

IN THE INTENSIVE CARE UNIT, APPROPRIATE MONITORING, WITH THE USE OF A PERIPHERAL NERVE STIMULATOR TO ASSESS THE DEGREE OF NEUROMUSCULAR BLOCKADE IS RECOMMENDED TO HELP PRECLUDE POSSIBLE PROLONGATION OF THE BLOCKADE. WHENEVER THE USE OF NORCURON® OR ANY NEUROMUSCULAR BLOCKING AGENT IS CONTEMPLATED IN THE ICU, IT IS RECOMMENDED THAT NEUROMUSCULAR TRANSMISSION BE MONITORED CONTINUOUSLY DURING ADMINISTRATION AND RECOVERY WITH THE HELP OF A NERVE STIMULATOR. ADDITIONAL DOSES OF NORCURON® OR ANY OTHER NEUROMUSCULAR BLOCKING AGENT SHOULD NOT BE GIVEN BEFORE THERE IS A DEFINITE RESPONSE TO T_1 OR TO THE FIRST TWITCH. IF NO RESPONSE IS ELICITED, INFUSION ADMINISTRATION SHOULD BE DISCONTINUED UNTIL A RESPONSE RETURNS.

Severe Obesity or Neuromuscular Disease: Patients with severe obesity or neuromuscular disease may pose airway and/or ventilatory problems requiring special care before, during and after the use of neuromuscular blocking agents such as Norcuron®.

Malignant Hyperthermia: Many drugs used in anesthetic practice are suspected of being capable of triggering a potentially fatal hypermetabolism of skeletal muscle known as malignant hyperthermia. There are insufficient data derived from screening in susceptible animals (swine) to establish whether or not Norcuron® is capable of triggering malignant hyperthermia.

C.N.S.: Norcuron® has no known effect on consciousness, the pain threshold or cerebration. Administration must be accompanied by adequate anesthesia or sedation.

Drug Interactions: Prior administration of succinylcholine may enhance the neuromuscular blocking effect of Norcuron® (vecuronium bromide) for injection and its duration of action. If succinylcholine is used before Norcuron®, the administration of Norcuron® should be delayed until the succinylcholine effect shows signs of wearing off. With succinylcholine as the intubating agent, initial doses of 0.04-0.06 mg/kg of Norcuron® may be administered to produce complete neuromuscular block with clinical duration of action of 25-30 minutes. The use of Norcuron® before succinylcholine, in order to attenuate some of the side effects of succinylcholine, has not been sufficiently studied.

Other nondepolarizing neuromuscular blocking agents (pancuronium, d-tubocurarine, metocurine, and gallamine) act in the same fashion as does Norcuron®, therefore these drugs and Norcuron® may manifest an additive effect when used together. There are insufficient data to support concomitant use of Norcuron® and other competitive muscle relaxants in the same patient.

Inhalational Anesthetics: Use of volatile inhalational anesthetics such as enflurane, isoflurane, and halothane with Norcuron® will enhance neuromuscular blockade. Potentiation is most prominent with use of enflurane and isoflurane. With the above agents the initial dose of Norcuron® may be the same as with balanced anesthesia unless the inhalational anesthetic has been administered for a sufficient time at a sufficient dose to have reached clinical equilibrium.

Antibiotics: Parenteral/intraperitoneal administration of high doses of certain antibiotics may intensify or produce neuromuscular block on their own. The following antibiotics have been associated with various degrees of paralysis: aminoglycosides (such as neomycin, streptomycin, kanamycin, gentamicin, and dihydrostreptomycin); tetracyclines; bacitracin; polymyxin B; colistin; and sodium colistimethate. If these or other newly introduced antibiotics are used in conjunction with Norcuron®, unexpected prolongation of neuromuscular block should be considered a possibility.

Other: Experience concerning injection of quinidine during recovery from use of other muscle relaxants suggest that recurrent paralysis may occur. This possibility must also be considered for Norcuron®. Norcuron® induced neuromuscular blockade has been counteracted by alkalosis and enhanced by acidosis in experimental animals (cat). Electrolyte imbalance and diseases which lead to electrolyte imbalance, such as adrenal cortical insufficiency, have been shown to alter neuromuscular blockade. Depending on the nature of the imbalance, either enhancement or inhibition may be expected. Magnesium salts, administered for the management of toxemia of pregnancy, may enhance the neuromuscular blockade.

Drug/laboratory test interactions: None known.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential or impairment of fertility.

Pregnancy: Pregnancy Category C: Animal reproduction studies have not been conducted with Norcuron®. It is also not known whether Norcuron® can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Norcuron® should be given to a pregnant woman only if clearly needed.

Pediatric Use: Infants under 1 year of age but older than 7 weeks, also tested under halothane anesthesia, are moderately more sensitive to Norcuron® on a mg/kg basis than adults and take about 1½ times as long to recover. Information presently available does not permit recommendations for usage in neonates.

ADVERSE REACTIONS: The most frequent adverse reaction to nondepolarizing blocking agents as a class consists of an extension of the drug's pharmacological action beyond the time period needed. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle paralysis resulting in respiration insufficiency or apnea.

Inadequate reversal of the neuromuscular blockade is possible with Norcuron® as with all curariform drugs. These adverse reactions are managed by manual or mechanical ventilation until recovery is judged adequate. Little or no increase in intensity of blockade or duration of action with Norcuron® is noted from the use of thiobarbiturates, narcotic analgesics, nitrous oxide, or droperidol. See OVERDOSAGE for discussion of other drugs used in anesthetic practice which also cause respiratory depression.

Prolonged to profound extensions of paralysis and/or muscle weakness as well as muscle atrophy have been reported after long-term use to support mechanical ventilation in the intensive care unit (see PRECAUTIONS).

The administration of Norcuron® has been associated with rare instances of hypersensitivity reactions (bronchospasm, hypotension and/or tachycardia, sometimes associated with acute urticaria or erythema).

OVERDOSAGE: The possibility of iatrogenic overdosage can be minimized by carefully monitoring muscle twitch response to peripheral nerve stimulation.

Excessive doses of Norcuron® produce enhanced pharmacological effects. Residual neuromuscular blockage beyond the time period needed may occur with Norcuron® as with other neuromuscular blockers. This may be manifested by skeletal muscle weakness, decreased respiratory reserve, low tidal volume, or apnea. A peripheral nerve stimulator may be used to assess the degree of residual neuromuscular blockade from other causes of decreased respiratory reserve.

Respiratory depression may be due either wholly or in part to other drugs used during the conduct of general anesthesia such as narcotics, thiobarbiturates and other central nervous system depressants. Under such circumstances, the primary treatment is maintenance of a patent airway and manual or mechanical ventilation until complete recovery of normal respiration is assured. Regonol® (pyridostigmine bromide) injection, neostigmine, or edrophonium, in conjunction with atropine or glycopyrrolate will usually antagonize the skeletal muscle relaxant action of Norcuron®. Satisfactory reversal can be judged by adequacy of skeletal muscle tone and by adequacy of respiration. A peripheral nerve stimulator may also be used to monitor restoration of

of prolonged neuromuscular blockade. Ventilation must be supported by artificial means until the patient has resumed cor of his respiration. Prior to the use of reversal agents, reference should be made to the specific package insert of the reversal age

DOSAGE AND ADMINISTRATION: Before prescribing, please consult complete product information. Norcuron® (vecuronium bromide) for injection is for intravenous use only. This drug should be administered by or under the supervision experienced clinicians familiar with the use of neuromuscular blocking agents. Dosage must be individualized in each cas dosage information which follows is derived from studies based upon units of drug per unit of body weight and is intende serve as a guide only, especially regarding enhancement of neuromuscular blockade of Norcuron® by volatile anesthetics by prior use of succinylcholine (see PRECAUTIONS/Drug Interactions). Parenteral drug products should be inspected vis for particulate matter and discoloration prior to administration whenever solution and container permit.

To obtain maximum clinical benefits of Norcuron® and to minimize the possibility of overdosage, the monitoring of mu twitch response to peripheral nerve stimulation is advised.

The recommended initial dose of Norcuron® is 0.08 to 0.10 mg/kg (1.4 to 1.75 times the ED_{90}) given as an intravenous injection. This dose can be expected to produce good or excellent non-emergency intubation conditions in 2.5 to 3 minu after injection. Under balanced anesthesia, clinically required neuromuscular blockade lasts approximately 25-30 minutes recovery to 25% of control achieved approximately 25 to 40 minutes after injection and recovery to 95% of control achie approximately 45-65 minutes after injection. In the presence of potent inhalation anesthetics, the neuromuscular block of Norcuron® is enhanced. If Norcuron® is first administered more than 5 minutes after the start of inhalation agent or steady state has been achieved, the initial Norcuron® dose may be reduced by approximately 15%, i.e., 0.060 to 0.08

Prior administration of succinylcholine may enhance the neuromuscular blocking effect and duration of action of N If intubation is performed using succinylcholine, a reduction of initial dose of Norcuron® to 0.04-0.06 mg/kg with inh anesthesia and 0.05-0.06 mg/kg with balanced anesthesia may be required.

During prolonged surgical procedures, maintenance doses of 0.010 to 0.015 mg/kg of Norcuron® are recommende initial Norcuron® injection, the first maintenance dose will generally be required within 25 to 40 minutes. However, cli ria should be used to determine the need for maintenance doses. Since Norcuron® lacks clinically important cumulati subsequent maintenance doses, if required, may be administered at relatively regular intervals for each patient, ranging imately from 12 to 15 minutes under balanced anesthesia, slightly longer under inhalation agents. (If less frequent adm tion is desired, higher maintenance doses may be administered.)

Should there be reason for the selection of larger doses in individual patients, initial doses ranging from 0.15 mg/kg 0.28 mg/kg have been administered during surgery under halothane anesthesia without ill effects to the cardiovascular s being noted as long as ventilation is properly maintained.

Use by Continuous Infusion: After an intubating dose of 80-100 μg/kg, a continuous infusion of 1 μg/kg/min can be i ated approximately 20-40 min later. Infusion of Norcuron® should be initiated only after early evidence of spontaneous rec from the bolus dose. Long-term intravenous infusion to support mechanical ventilation in the intensive care unit has not be studied sufficiently to support dosage recommendations (see PRECAUTIONS).

The infusion of Norcuron® should be individualized for each patient. The rate of administration should be adjusted acc to the patient's twitch response as determined by peripheral nerve stimulation. An initial rate of 1 μg/kg/min is recommen with the rate of the infusion adjusted thereafter to maintain a 90% suppression of twitch response. Average infusion rates range from 0.8 to 1.2 μg/kg/min.

Inhalation anesthetics, particularly enflurane and isoflurane may enhance the neuromuscular blocking action of non-depolarizing muscle relaxants. In the presence of steady-state concentrations of enflurane or isoflurane, it may be necessa reduce the rate of infusion 25-60 percent, 45-60 min after the intubating dose. Under halothane anesthesia it may not be essary to reduce the rate of infusion.

Spontaneous recovery and reversal of neuromuscular blockade following discontinuation of Norcuron® infusion may be expected to proceed at rates comparable to that following a single bolus dose.

Infusion solutions of Norcuron® can be prepared by mixing Norcuron® with an appropriate infusion solution such as 5 glucose in water, 0.9% NaCl, 5% glucose in saline, or Lactated Ringers. Unused portions of infusion solutions should be discarded.

Infusion rates of Norcuron® can be individualized for each patient using the following table:

Drug Delivery Rate (μg/kg/min)	Infusion Delivery Rate (mL/kg/min)	
	0.1 mg/mL*	0.2 mg/mL†
0.7	0.007	0.0035
0.8	0.008	0.0040
0.9	0.009	0.0045
1.0	0.010	0.0050
1.1	0.011	0.0055
1.2	0.012	0.0060
1.3	0.013	0.0065

*10 mg of Norcuron® in 100 mL solution †20 mg of Norcuron® in 100 mL solution

The following table is a guideline for mL/min delivery for a solution of 0.1 mg/mL (10 mg in 100 mL) with an infusion pum

NORCURON® INFUSION RATE – mL/MIN

Amount of Drug μg/kg/min	Patient Weight – kg						
	40	50	60	70	80	90	1
0.7	0.28	0.35	0.42	0.49	0.56	0.63	(
0.8	0.32	0.40	0.48	0.56	0.64	0.72	0.
0.9	0.36	0.45	0.54	0.63	0.72	0.81	0.
1.0	0.40	0.50	0.60	0.70	0.80	0.90	1.
1.1	0.44	0.55	0.66	0.77	0.88	0.99	1
1.2	0.48	0.60	0.72	0.84	0.96	1.08	1
1.3	0.52	0.65	0.78	0.91	1.04	1.17	

NOTE: If a concentration of 0.2 mg/mL is used (20 mg in 100 mL), the rate should be decreased by one-half.

Dosage in Children: Older children (10 to 17 years of age) have approximately the same dosage requirements (mg adults and may be managed the same way. Younger children (1 to 10 years of age) may require a slightly higher initial may also require supplementation slightly more often than adults. Infants under one year of age but older than 7 week moderately more sensitive to Norcuron® on a mg/kg basis than adults and take about 1½ times as long to recover. See subsection of PRECAUTIONS titled Pediatric Use. Information presently available does not permit recommendation on neonates (see PRECAUTIONS). There are insufficient data concerning continuous infusion of vecuronium in children, th no dosing recommendation can be made.

COMPATIBILITY: Norcuron® is compatible in solution with:

0.9% NaCl solution	Sterile water for injection	Lactated Ringers
5% glucose in water	5% glucose in saline	

Use within 24 hours of mixing with the above solutions.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administratio ever solution and container permit.

HOW SUPPLIED:

10 mL vials (10 mg vecuronium bromide) and 10 mL prefilled syringes of diluent (bacteriostatic water for injection, US 22 g 1¼" needle. Boxes of 10 NDC No. 0052-0441-60

10 mL vials (10 mg vecuronium bromide) and 10 mL vials of diluent (bacteriostatic water for injection, USP). Boxes of 10 NDC No. 0052-0441-17

10 mL vials (10 mg vecuronium bromide) only; DILUENT NOT SUPPLIED. Boxes of 10 NDC No. 0052-0441

20 mL vials (20 mg vecuronium bromide) only; DILUENT NOT SUPPLIED. Boxes of 10 NDC No. 0052-044

STORAGE: 15°-30°C (59°-86°F). Protect from light.

AFTER RECONSTITUTION:

- When reconstituted with supplied bacteriostatic water for injection: CONTAINS BENZYL ALCOHOL, WHICH IS NOT INTENDED FOR USE IN NEWBORNS. Use within 5 days. May be stored at room temperature or refrigerated.
- When reconstituted with sterile water for injection or other compatible I.V. solutions: Refrigerate vial. Use within 24 Single use only. Discard unused portion.

Caution: Federal law prohibits dispensing without prescription. REVIS

IARS 67th CONGRESS

MARCH 19 -23, 1993

San Diego Marriott Hotel & Marina

INTERNATIONAL ANESTHESIA RESEARCH SOCIETY

TUTORIALS

The Program Committee is pleased to announce an extensive Tutorial Program which features small schoolroom sessions that offer opportunities for informal discussions with the experts.

The 67th Congress topics include: Ambulatory Anesthesia; Deep Hypothermic Circulatory Arrest; Fiberoptic Bronchoscopy; Resident Education; Hemodynamic Misadventures; Running a Pain Service; Practice Opportunities; Regional Blocks; Statistics; TEE for the Neophyte; TEE Advanced Applications.

Detailed program information will be sent to all IARS members in December, 1992.

“We’re just like the Bair Hugger®”

Imitation is the sincerest form of flattery… but wouldn’t you rather have the tested, the proven, the published, the original — “the Bair Hugger?” Bair Hugger® Therapy revolutionized patient warming five years ago. Now, a number of imitators are introducing convective warming products.

Consider the differences. Only Bair Hugger Warming’s unique design *hugs*, surrounding the patient with warm air for maximum heat transfer. Bair Hugger Blankets are made of recycled tissue, soft against your patient’s skin and environmentally responsible. Only Bair Hugger Therapy has been *proven* effective in fifteen independent studies. And only Bair Hugger Warming can claim over two million safe and effective patient therapies. Don’t your patients deserve a hug today? Bair Hugger® Warming Therapy. From Augustine Medical, Inc.

ANESTHESIA & ANALGESIA

Journal of the International Anesthesia Research Society

The **International Anesthesia Research Society** is a nonprofit, scientific, and educational corporation in the state of Ohio. Members of the Board of Trustees of the Society are: David R. Bevan, MA, MB, BChir, Michael K. Cahalan, MD, Douglas B. Craig, MD, FRCPC, Bruce F. Cullen, MD, Noel W. Lawson, MD, Edward D. Miller, Jr, MD, Dean H. Morrow, MD, Joseph G. Reves, MD, Robert K. Stoelting, MD, Stephen J. Thomas, MD, John L. Waller, MD, and K. C. Wong, MD, PhD. Emeritus Trustees are: E. Paul Didier, MD, Paul R. Dumke, MD, John T. Martin, MD, Emerson A. Moffitt, MD, Morris J. Nicholson, MD, and B. B. Sankey, MD.

Anesthesia & Analgesia (ISSN 0003-2999) is issued monthly for the IARS in two indexed volumes per year by Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010. Printed in USA. © 1992 by the International Anesthesia Research Society. Second class postage paid at New York, NY and at additional mailing offices.

Subscription information for 1992 applying to IARS members: USA and possessions, $95.00 per year; in all other countries, $120.00. Membership is available to individuals with doctorate degrees in medicine, osteopathy, dentistry, veterinary medicine, or other disciplines who are engaged in active clinical practice of or research in anesthesiology. Associate Membership is available to individuals certified, licensed, or accredited by anesthesia-related professions (CRNA, CRTT, RRT, Physician Assistant). Educational Membership (at a reduced price) is available to interns, residents, and students in nurse anesthesia and related training programs, for a 2-, 3-, or 4-year period upon completion of application including certification by applicant's program director.

All membership payments and correspondence regarding IARS member subscriptions should be sent to: International Anesthesia Research Society, Suite 140, 2 Summit Park Drive, Cleveland, OH 44131-2553.

Subscription information for 1992 applying to non-IARS members: Institutions, $150.00; nonmember individuals, $110.00. Outside the USA and possessions, please add $35.00 for surface postage and handling. For airmail, add $80.00 in USA, Canada, and Mexico; $70.00 for surface airlift to Europe; $85.00 for surface airlift to Japan; and $160.00 for airmail to the rest of the world. Postmaster: Send address changes to: *Anesthesia & Analgesia*, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

Orders and inquiries regarding institutional and nonmember individual subscriptions should be directed to: Journals Fulfillment, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

Single issues: Single copy information is available from Elsevier Science Publishing Co., Inc., upon request. Back volume (all issues prior to 1983) information is available from the IARS.

Advertising inquiries should be addressed to: Pharmaceutical Media, Inc., 440 Park Avenue South, 14th Floor, New York, NY 10016. Although all advertising material is expected to conform to ethical (medical) standards, inclusion in this publication does not constitute a guarantee or endorsement of the quality or value of such product or of the claim made of it by its manufacturer.

No responsibility is assumed by the Publisher for any injury and/or damage to persons or property as a matter of products liability, negligence, or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein. No suggested test or procedure should be carried out unless, in the reader's judgment, its risk is justified. Because of rapid advances in the medical sciences, we recommend that the independent verification of diagnoses and drug dosages should be made. Discussions, views, and recommendations as to medical procedures, choice of drugs, and drug dosages are the responsibility of the authors.

See Classified Ads section for submission of classified ad material.

All articles published in this journal become the property of the International Anesthesia Research Society. This journal has been registered with the **Copyright Clearance Center, Inc.** Consent is given for the copying of articles for personal or internal use, or for the personal or internal use of specific clients. This consent is given on the condition that the copier pay through the center the per copy fee stated in the code on the first page of each article for copying beyond that permitted by the US Copyright Law. The appropriate fee should be forwarded with a copy of the first page of the article to the Copyright Clearance Center, Inc., 27 Congress Street, Salem, MA 01970. If no code appears on an article, the author has not given broad consent to copy, and permission to copy must be obtained directly from the author. This consent does not extend to other kinds of copying, such as for general distribution, resale, advertising and promotional purposes, or for creating new collective works.

All inquiries regarding copyrighted material from this publication, other than reproduction through the Copyright Clearance Center, should be directed to: Rights and Permissions Department, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010. FAX 212-633-3977.

Reprints: For single copies, write directly to the senior author at the address listed on the title page. Quantity orders (minimum 100) are processed through Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010. Prices are provided upon request.

This journal is abstracted/indexed in: Biological Abstracts, Chemical Abstracts, Cumulative Index to Nursing & Allied Health Literature (CINAHL), Current Contents/Life Sciences, Current Contents/Clinical Practice, Excerpta Medica, Index Medicus, ISI/Biomed, and Science Citation Index.

On line text is available through **BRS Colleague**, 8000 Westpark Drive, McLean, VA 22102. Telephone: (800) 289-4277.

This journal is printed on acid-free paper.

Nurse Anesthetist

Premium Pay
Premium Location

Located in historic Princeton, New Jersey, the Medical Center, a 450-bed teaching community hospital, offers the perfect setting for your professional practice!

Complement our staff of anesthesiologists and CRNA's, dedicated to its patients, staff and community. N.J. license and AANA certification required.

For more information regarding this exceptional **Full-time** opportunity with flexible scheduling, please contact:

Yolanda M. Lahaza, Assistant Director
253 Witherspoon St., Princeton, NJ 08540
609-497-4338

Equal Opportunity Employer M/F

Where tradition & innovation meet.

PRINCETON

(OCHSNER LOGO)

ANESTHESIOLOGIST OPENINGS

Positions are available at the Ochsner Clinic New Orleans and Ochsner Clinic Baton Rouge for BC/BE anesthesiologists.

Ochsner Clinic New Orleans:

- Generalists
- Intensivist Medical Director for 32-bed medical surgical ICU

Ochsner Clinic Baton Rouge:

- Generalists
- Pain
- Critical Care

Ochsner offers a very competitive salary, rich fringe benefits package, two substantial retirement programs, excellent paid vacation and CME time, all malpractice insurance provided, and opportunity for partnership status. Send CV to:

Ochsner Clinic

INTERNATIONAL ANESTHESIA RESEARCH SOCIETY

THE B.B. SANKEY ANESTHESIA ADVANCEMENT AWARDS

1993 B.B. SANKEY ANESTHESIA ADVANCEMENT AWARDS

Applications for up to $25,000 are invited for the 1993 Awards, subject to the following basic conditions:

- Proposals must be within the general field of anesthesiology and may be for research, clinical care, education, or administration.
- Applicants must be members of the International Anesthesia Research Society.
- Applications must be received in the IARS Cleveland office no later than December 11, 1992. Where relevant, applications must include institutional approval of human studies and/or animal research.
- The official application for the Award must be used. This form, as well as the guidelines for applicants, is available on request to:

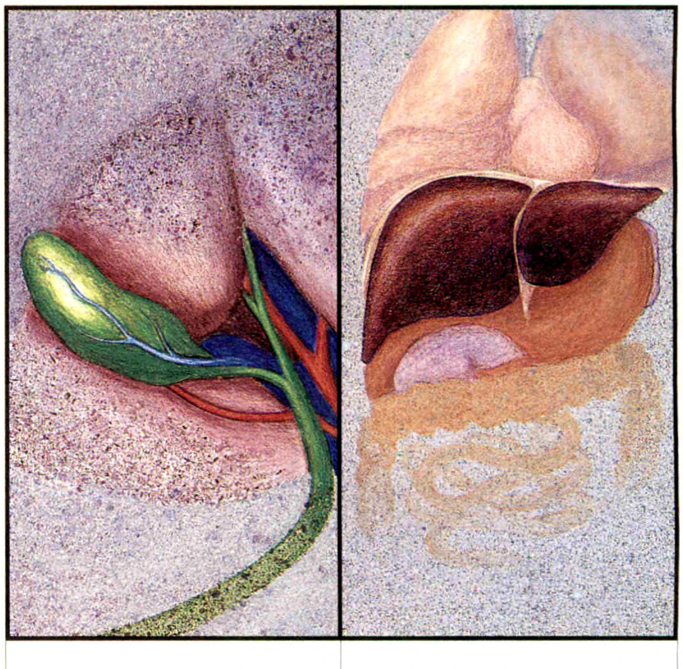
International Anesthesia Research Society
2 Summit Park Dr., #140
Cleveland, OH 44131
Telephone: (216) 642-1124

The 1993 Awards will be announced at the 67th Congress of the International Anesthesia Research Society to be held at the San Diego Marriott, March 19–23, 1993.

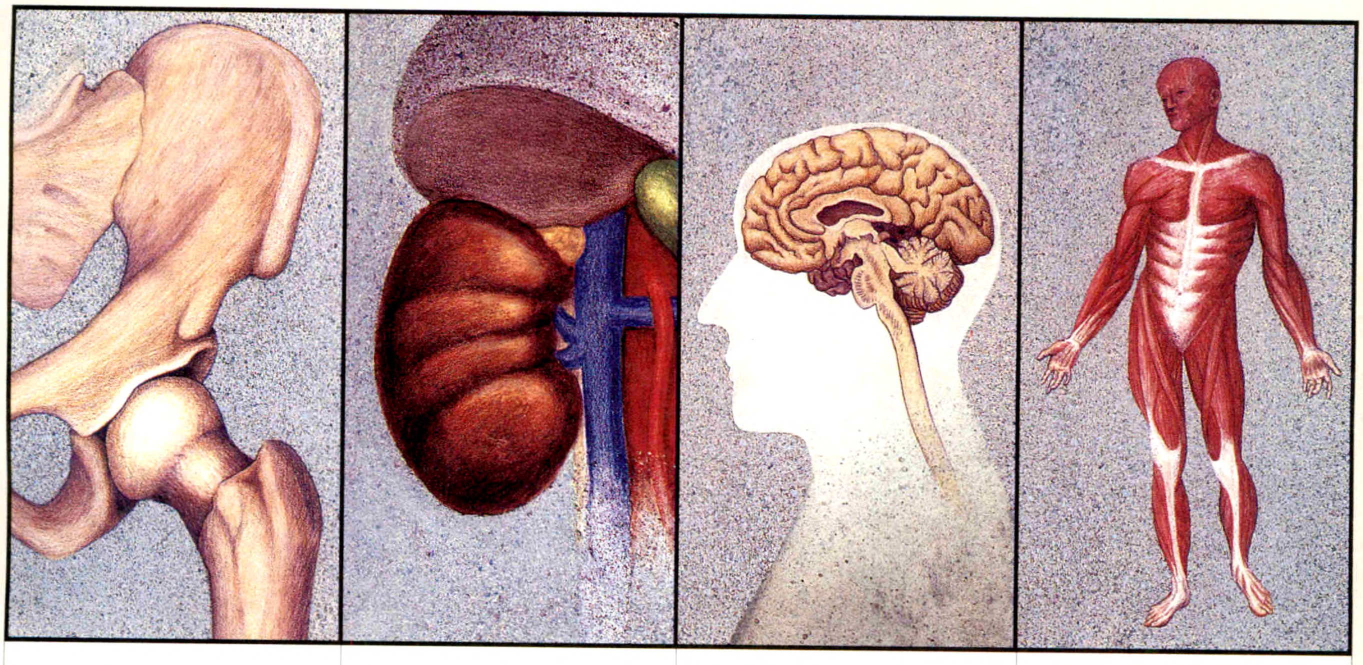
Tracrium®

For many procedures

For many reasons



Cholecystectomy	Biliary tract repair
Common patient type Obese	**Common patient type** Both adults and children
Advantage of Tracrium No difference in recovery from neuromuscular blockade between normal and obese patients.[1]	**Advantage of Tracrium** Clinical response unaffected by hepatic function[2] or patient age.[3]



Total hip replacement	**Renal surgery**	**Neurosurgery for trauma**	**Everyday procedures**
Common patient type Elderly women and men	**Common patient type** Both adults and children	**Common patient type** Both adults and children	**Common patient type** Average
Advantage of Tracrium Recovery time unaffected by age.[3]	**Advantage of Tracrium** Recovery time unaffected by renal dysfunction.[2]	**Advantage of Tracrium** Effect unchanged by concomitant anticonvulsant medications (phenytoin, carbamazepine).[4,5]	**Advantage of Tracrium** The same reasons Tracrium is ideal for special patient types make it the choice for everyday procedures.

TRACRIUM® INJECTION

(atracurium besylate) 10 mg/mL

For predictable recovery

TR-Y03368

See brief summary of prescribing information on adjacent page.

TRACRIUM® INJECTION
(atracurium besylate)

Brief Summary
This drug should be used only by adequately trained individuals familiar with its actions, characteristics, and hazards.

INDICATIONS AND USAGE: Tracrium is indicated, as an adjunct to general anesthesia, to facilitate endotracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation.

CONTRAINDICATIONS: Tracrium is contraindicated in patients known to have a hypersensitivity to it.

WARNINGS: TRACRIUM SHOULD BE USED ONLY BY THOSE SKILLED IN AIRWAY MANAGEMENT AND RESPIRATORY SUPPORT. EQUIPMENT AND PERSONNEL MUST BE IMMEDIATELY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND SUPPORT OF VENTILATION, INCLUDING ADMINISTRATION OF POSITIVE PRESSURE OXYGEN. ADEQUACY OF RESPIRATION MUST BE ASSURED THROUGH ASSISTED OR CONTROLLED VENTILATION. ANTICHOLINESTERASE REVERSAL AGENTS SHOULD BE IMMEDIATELY AVAILABLE. DO NOT GIVE TRACRIUM BY INTRAMUSCULAR ADMINISTRATION. Tracrium has no known effect on consciousness, pain threshold, or cerebration. It should be used only with adequate anesthesia. Tracrium Injection, which has an acid pH, should not be mixed with alkaline solutions (e.g., barbiturate solutions) in the same syringe or administered simultaneously during intravenous infusion through the same needle. Depending on the resultant pH of such mixtures, Tracrium may be inactivated and a free acid may be precipitated. Tracrium Injection 10 mL multiple dose vials contain benzyl alcohol. Benzyl alcohol has been associated with an increased incidence of neurological and other complications in newborn infants which are sometimes fatal. Tracrium Injection 5 mL ampuls and 5 mL single use vials do not contain benzyl alcohol.

PRECAUTIONS: General: Although Tracrium is a less potent histamine releaser than d-tubocurarine or metocurine, the possibility of substantial histamine release in sensitive individuals must be considered. Special caution should be exercised in administering Tracrium to patients in whom substantial histamine release would be especially hazardous (e.g., patients with clinically significant cardiovascular disease) and in patients with any history (e.g., severe anaphylactoid reactions or asthma) suggesting a greater risk of histamine release. In these patients, the recommended initial Tracrium dose is lower (0.3 to 0.4 mg/kg) than for other patients and should be administered slowly or in divided doses over one minute. Since Tracrium has no clinically significant effects on heart rate in the recommended dosage range, it will not counteract the bradycardia produced by many anesthetic agents or vagal stimulation. As a result, bradycardia during anesthesia may be more common with Tracrium than with other muscle relaxants. Tracrium may have profound effects in patients with myasthenia gravis, Eaton-Lambert syndrome, or other neuromuscular diseases in which potentiation of nondepolarizing agents has been noted. The use of a peripheral nerve stimulator is especially important for assessing neuromuscular blockade in these patients. Similar precautions should be taken in patients with severe electrolyte disorders or carcinomatosis. Multiple factors in anesthesia practice are suspected of triggering malignant hyperthermia (MH), a potentially fatal hypermetabolic state of skeletal muscle. Halogenated anesthetic agents and succinylcholine are recognized as the principal pharmacologic triggering agents in MH-susceptible patients; however, since MH can develop in the absence of established triggering agents, the clinician should be prepared to recognize and treat MH in any patient scheduled for general anesthesia. Reports of MH have been rare in cases in which Tracrium has been used. In studies of MH-susceptible animals (swine) and in a clinical study of MH-susceptible patients, Tracrium did not trigger this syndrome. Resistance to nondepolarizing neuromuscular blocking agents may develop in burn patients. Increased doses of nondepolarizing muscle relaxants may be required in burn patients and are dependent on the time elapsed since the burn injury and the size of the burn. The safety of Tracrium has not been established in patients with bronchial asthma. **Long-Term Use in Intensive Care Unit (ICU):** Tracrium has been used to facilitate mechanical ventilation in ICU patients. When there is a need for long-term mechanical ventilation, the benefits to risk ratio of neuromuscular blockade must be considered. There is only limited information on the efficacy and safety of Tracrium administered by long-term (days to weeks) intravenous infusion to facilitate mechanical ventilation in intensive care facilities. For Tracrium, as with other neuromuscular blocking agents used in intensive care facilities, available evidence suggests that there is wide interpatient variability in dosage requirements and that these requirements may change with time. Limited data suggest that Tracrium infusion requirements may increase with prolonged administration in the ICU. As with other neuromuscular blocking agents, little information is available on the plasma levels or clinical consequences of atracurium metabolites following long-term (days to weeks) infusion of Tracrium in the intensive care unit setting. One metabolite of atracurium, laudanosine, when administered alone to laboratory animals, has been associated with cerebral excitatory effects. Physiological effects of laudanosine in humans have not been demonstrated. The effects of hemodialysis, hemoperfusion and hemofiltration on plasma levels of atracurium and its metabolites are unknown. **Drug Interactions:** Drugs which may enhance neuromuscular blocking action of Tracrium include: enflurane; isoflurane; halothane; certain antibiotics, especially the aminoglycosides and polymyxins; lithium; magnesium salts; procainamide; and quinidine. If other muscle relaxants are used during the same procedure, the possibility of a synergistic or antagonist effect should be considered. The prior administration of succinylcholine does not enhance the duration, but quickens the onset and may increase the depth, of neuromuscular blockade induced by Tracrium. Tracrium should not be administered until a patient has recovered from succinylcholine-induced neuromuscular blockade. **Carcinogenesis, Mutagenesis, Impairment of Fertility:** A positive response was observed in the mouse lymphoma assay under conditions which killed over 80% of the treated cells. A far weaker response was observed in the presence of metabolic activation at concentrations which also killed over 80% of the treated cells. **Pregnancy: *Teratogenic Effects:*** Pregnancy Category C. Tracrium has been shown to be potentially teratogenic in rabbits, when given in doses up to approximately one-half the human dose. There are no adequate and well-controlled studies in pregnant women. Tracrium should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Labor and Delivery:** It is not known whether muscle relaxants administered during vaginal delivery have immediate or delayed adverse effects on the fetus or increase the likelihood that resuscitation of the newborn will be necessary. The possibility that forceps delivery will be necessary may increase. Tracrium (0.3 mg/kg) has been administered to 26 pregnant women during delivery by cesarean section. No harmful effects were attributable to Tracrium in any of the newborn infants, although small amounts of Tracrium were shown to cross the placental barrier. The possibility of respiratory depression in the newborn infant should always be considered following cesarean section during which a neuromuscular blocking agent has been administered. In patients receiving magnesium sulfate, the reversal of neuromuscular blockade may be unsatisfactory and Tracrium dose should be lowered as indicated. **Nursing Mothers:** It is not known whether this drug is excreted in human milk. Caution should be exercised when Tracrium is administered to a nursing woman. **Pediatric Use:** Safety and effectiveness in children below the age of 1 month have not been established.

ADVERSE REACTIONS: Observed in Controlled Clinical Studies: Tracrium produced few adverse reactions during extensive clinical trials. Most were suggestive of histamine release (see Precautions Section). The overall incidence rate for clinically important adverse reactions was 7/875 or 0.8%. Most adverse reactions were of little clinical significance unless they were associated with significant hemodynamic changes. Substantial vital sign changes greater than or equal to 30% observed in 530 patients, without cardiovascular disease, were as follows: in those patients given the recommended initial dosage range of 0.31 to 0.50 mg/kg of Tracrium, mean arterial pressure increased in 2.8% and decreased in 2.1% of patients while the heart rate increased in 2.8% of these patients. At doses of ≥ 0.60 mg/kg, 14.3% of the studied patients had a decrease in mean arterial pressure while 4.8% had an increase in heart rate. At doses ≤ 0.30 mg/kg, mean arterial pressure increased in 1.9% and decreased in 1.1% of patients, while heart rate increased in 1.6% and decreased in 0.8% of these patients. **Observed in Clinical Practice:** Based on clinical experience in the U.S. and the United Kingdom of approximately 3 million patients given Tracrium the following adverse reactions are among the most frequently reported: *General:* allergic reactions (anaphylactic or anaphylactoid) which, in rare instances, were severe (e.g., cardiac arrest); *Musculoskeletal:* inadequate, prolonged block; *Cardiovascular:* hypotension, vasodilatation (flushing), tachycardia, bradycardia; *Respiratory:* dyspnea, bronchospasm, laryngospasm; *Integumentary:* rash, urticaria, injection site reaction.

STORAGE: Tracrium Injection should be refrigerated at 2° to 8° C (36° to 46° F) to preserve potency. DO NOT FREEZE. Upon removal from refrigeration to room temperature storage conditions (25° C/77° F), use Tracrium Injection within 14 days even if rerefrigerated.

EUROANAESTHESIA '93

March 26 - 27, 1993, Bern University of Bern, Switzerland,
Department of Anaesthesiology and Intensive Care

Sponsored by the European Academy of Anaesthesiology

Quality Assurance in Clinical Anaesthesia

This symposium will deal with an essential part of Clinical Anaesthesia - Quality Control - which will gain in importance in the next years. An exchange of experience is desirable, especially for clinics thinking to introduce some sort of quality control in the next future. Some of the topics are:

- What are the risks of modern anaesthesia?
- How can modern technology help prevent mishaps?
- Do there exist "dangerous" anaesthesiologists?
- Will new standards improve safety?

Ask for a preliminary programme! For further information please contact:
IFAI Institut für Anästhesiologie und Intensivbehandlung,
Inselspital, CH-3010 Bern, Switzerland. Fax +31/25.62.85

— THE BEN COVINO RESEARCH AWARD —

Applications for up to $10,000 are invited for the 1993 Ben Covino Award, subject to the following basic conditions:

- The proposal should primarily relate to the use of local anesthetics/regional anesthesia, specifically within the preclinical and explorative clinical research fields.
- Applications to the Covino Award Committee must be received in the IARS Cleveland office no later than November 20, 1992. Where relevant, applications must include institutional approval of human studies and/or animal research.
- The official application for the Award must be used. This form, as well as the guidelines for applicants, is available on request to:

International Anesthesia Research Society
2 Summit Park Drive, Suite 140
Cleveland, OH 44131
USA
Telephone: (216) 642-1124

The establishment of the Ben Covino Award was announced at the 1992 Annual Scientific Meeting of the International Anesthesia Research Society held at the San Francisco Hilton. The Ben Covino Award has been instituted by Astra Pain Control, Sweden.

EDITORIAL

Pharmacology of Hemostasis in the Surgical Patient

David R. Jobes, MD, and Norig Ellison, MD
Department of Anesthesiology, University of Pennsylvania, Philadelphia, Pennsylvania

In this issue of *Anesthesia & Analgesia*, Guay et al. (1) report the failure of desmopressin administration to decrease the volume of blood lost or units of blood transfused in patients undergoing spinal fusion for idiopathic scoliosis. The 1986 report by Salzman et al. (2) that desmopressin administration significantly improved hemostasis and decreased blood loss in patients undergoing cardiac surgery associated with large blood loss generated considerable interest in the pharmacology of hemostasis. Subsequent desmopressin studies of similar quality and magnitude in both cardiac and noncardiac surgery have yielded conflicting results (3–5). Does the current report further refute the Salzman study? More properly, the question is, where is desmopressin therapy most likely to be beneficial?

Originally developed for use in the treatment of patients with diabetes insipidus, desmopressin is a synthetic polypeptide analogue of the antidiuretic hormone vasopressin but lacks the vasoconstrictor properties of the latter. Independent observations by Cash et al. (6) and Mannucci et al. (7) that desmopressin increases Factor VIII:C and Factor VIII:vWF concentrations in normal volunteers introduced a new indication for this drug, an indication that today greatly exceeds its original use. Of note, adrenalin, insulin, vasopressin, and nicotine are also capable of increasing the concentration of Factor VIII:C, but undesirable side effects preclude their clinical use for this purpose.

The rapid increase in Factor VIII:C and Factor VIII:vWF concentrations after desmopressin administration suggests that it induces a brisk release of preformed proteins from endogenous stores rather than synthesis of new factors. The observation of progressively poorer responses after repeated administrations (tachyphylaxis) supports this suggestion. Desmopressin has decreased bleeding time or blood loss, or both, in a wide variety of nonspecific conditions, including uremia, Factor IX deficiency, cirrhosis, and platelet dysfunction induced by some drugs. However, desmopressin has proved ineffective in other conditions, such as Glanzmann's thrombasthenia, storage pool deficiency, and thrombocytopenia (8).

It appears that desmopressin is most likely (but not always) to have a beneficial effect where some preexisting condition exists. The Salzman study suggests specifically that a low "normal" Factor VIII:vWF starting level, a cardiopulmonary bypass time >2 h, and an average blood loss >2 L are such conditions (2). This indeed is a very specific, small population of patients in our experience, because few of our patients (including those with aspirin ingestion up to the time of surgery) will lose >2 L of blood without desmopressin administration. Perhaps the inclusion of reoperation answers the question but then further limits the population in whom desmopressin will be effective. Similarly, others have concluded that when applied to a more general population of cardiac surgical patients, desmopressin cannot be shown to have this effect (3,4). The results of Guay et al. (1) similarly identify a subset of patients with scoliosis who are not benefitted by desmopressin. It is clear that desmopressin is unlikely to be beneficial simply because the surgical procedures are associated with large blood losses or procedurally induced platelet dysfunction. More work needs to be done to identify more clearly the patients who will benefit from this drug. Ideally, a test to identify these patients should be developed. It most certainly can be concluded that desmopressin should not become part of a "shotgun approach" in the treatment of excessive bleeding associated with any operative procedure.

The results of this study and others clearly point out that there is no pharmacologic substitute for the three essentials in the hemostatic management of every surgical patient:

1. *A properly taken history and thorough physical examination are the best means of detecting a hemorrhagic diathesis*, be it congenital or acquired. Seeking a patient's hemostatic response to any previous surgical experience is often overlooked in taking the history.

Accepted for publication May 8, 1992.

2. *A screening hemostatic laboratory profile on any patient whose history and physical examination suggest a possible problem with hemostasis.* Additionally, in surgical procedures where there is the potential for large blood loss, such as cardiac surgery and spinal fusion, such a profile will alert physicians to potential problem patients as well as provide a baseline set of tests for comparison should excessive bleeding intraoperatively require additional tests.
3. *Meticulous surgical hemostasis,* without which no amount of questioning, testing, pharmacology, or blood products can provide effective hemostasis.

Finally, in comparing apparently conflicting reports of efficacy in improving hemostasis, the volume of blood transfused may be the most accurate and clinically important measurement of efficacy. Although morbidity may be associated with any significant bleeding, it is entirely another level of concern when the blood lost requires transfusion of homologous blood products. Estimates of intraoperative blood loss are notoriously inaccurate, and only in the case of postoperative losses collected in containers (e.g., chest tube drainage) is accuracy achieved consistently. In evaluating conflicting reports, one must keep in mind that the size of the study population needed to establish a statistical difference is greater for blood transfusion than for blood loss. Groups of patients who start with the same hemoglobin and are transfused to maintain the same target hemoglobin will show a statistically significant difference if the drug or regimen being studied is effective (5). Today, "the current re-emphasis on transmission of viral disease via transfusion suggests . . . clinically important bleeding must include any need for transfusion" (9).

Adenosine for Controlled Hypotension: Systemic Comparec With Intracoronary Infusion in Dogs

Avner Sidi, MD, and William Rush, BA

Department of Anesthesiology, University of Florida College of Medicine, Gainesville, Florida

We hypothesized that either through local myocardial or systemic effects, adenosine could be used to control hypotension during ischemia. Therefore, we compared the effects of systemic with intracoronary infusion of adenosine on myocardial hemodynamics and metabolism during ischemia in 27 dogs. Left anterior descending artery (LADa) flow was measured and the LADa constricted by a micrometer to restrict resting flow by 50%, 75%, and 100%. Adenosine was infused either systemically ($n = 9$), to maintain mean aortic pressure at 50–60 mm Hg, or directly into the LADa ($n = 9$), to create maximal coronary hyperperfusion; no adenosine was infused in the control group ($n = 9$). With systemic adenosine, during each constriction aortic pressure, left ventricular first derivative (LV dP/dt), and heart rate (HR) decreased: aortic pressure by 56.1% ± 2.9% (mean ± SEM), LV dP/dt by 36.2% ± 2.2%, systemic resistance by 42.7% ± 5%, and HR by 38.7% ± 3% during 50% constriction ($P < 0.05$ for each variable). Intracoronary adenosine decreased only aortic pressure, LV dP/dt, and HR, all to a lesser extent: aortic pressure by 5% ± 2.8%, LV dP/dt by 15% ± 1.2%, and HR by 4.6% ± 1.7% ($P < 0.05$, compared with systemic adenosine for each variable). With systemic adenosine only in the nonischemic area, regional myocardial blood flow increased and remained high, from 224.6 ± 65.2 to 342 ± 46.2 $\text{mL}\cdot\text{min}^{-1}\cdot 100\ \text{g}^{-1}$ during 50% constriction ($P < 0.05$); with intracoronary adenosine, ischemic zone regional myocardial blood flow increased, but not consistently. In the ischemic area, O_2 consumption was less with than without systemic adenosine; also, lactate flux production was less positive (−60.2 ± 37.6 compared with 80.3 ± 20.2 $\text{mmol}\cdot\text{min}^{-1}\cdot 100\ \text{g}^{-1} \times 10^{-3}$ during 50% constriction; $P < 0.05$). Systemic infusion of adenosine during coronary hypoperfusion improves regional metabolism during ischemia and, thus, may mitigate myocardial ischemia. The mechanism by which systemic infusion improves metabolic status may be by decreases in both systemic pressure and systemic vascular resistance.

(Anesth Analg 1992;75:319–28)

Primarily an arterial and coronary vasodilator (1) and a sinus node inhibitor (2), adenosine can be used for controlled hypotension (3) and may counter hemodynamic and metabolic impairment (4) during myocardial ischemia. Adenosine may also produce intramyocardial redistribution (5) and "steal" (6). The ratio of O_2 supply to demand, however, plays a major part in adenosine production by the heart (7). When an imbalance occurs, as during hypoxia or ischemia, the myocardium releases adenosine in an amount sufficient to depress myocardial conduction and activity (8), which restores the ba ance of the supply/demand ratio. Endogenous c exogenous adenosine can retard ischemia by one c two mechanisms: by means of special receptors (atr al, ventricular, or even endothelial) (9) or by preven ing metabolic changes in myocardial cells, eithe directly by affecting adenosine triphosphate (AT (10,11) or indirectly by simulating glycolysis an glucose uptake, which increases cellular ATP (12 The specific receptor mechanism may be identified b analyzing the role of systemic hemodynamic variables (for example, pressure, resistance, and heart rat [HR]) in the metabolic response to ischemia. Also, th metabolic effect of adenosine can be evaluated b examining its direct effect on the myocardial metabolic variables, glucose uptake, and consumption c O_2 and lactate.

Adenosine may be a useful agent to induce hypotension in patients with ischemic heart disease Therefore, the rationale for undertaking this stud was to evaluate whether using adenosine to induc

hypotension during ischemia would be beneficial and, if so, to identify the mechanism of action: local myocardial or systemic-peripheral. We hypothesized that adenosine may minimize regional metabolic impairment during myocardial ischemia. The amount of adenosine, however, was likely to be critical because too much in the coronary circulation could induce steal, and a systemic overdose, simply by decreasing arterial pressure, might decrease both O_2 and blood supply. By a method previously used to study nitroglycerin clinically (13), we compared the hemodynamic and regional metabolic effects of systemic infusion of adenosine with those of intracoronary infusion of adenosine during partial or complete constriction of the left anterior descending artery (LADa) in a canine model of acute coronary artery occlusion (14,15).

Methods

The study was approved by the appropriate institutional review board; animal resource facilities in which this research was conducted are fully accredited by the American Association for Accreditation of Laboratory Animal Care.

Surgical Preparation

Adult male and female mongrel dogs (n = 35), weighing 21–30 kg, received thiamylal (10–15 mg/kg), followed by a continuous infusion of 1–4 $mg \cdot kg^{-1} \cdot h^{-1}$. Each dog was mechanically ventilated with an air/O_2 mixture to maintain normoxia and normocarbia. Catheters were introduced into the pulmonary artery (PA) and aorta (Ao) from the femoral vein and artery, respectively, to measure cardiac output (by thermodilution technique) and pressures. After a left fifth interspace thoracotomy, the heart was suspended in a pericardial cradle. The left ventricle (LV) was cannulated from its apex with a transducer-tipped catheter (Millar) to measure LV pressure and its first derivative (LV dP/dt). The left atrium was cannulated by a rigid catheter for microsphere injection.

The LADa was isolated proximal to the first major apical diagonal branch and loosely encircled by a cardiac pacing wire coated with a polyvinyl chloride ligature (the wire came originally with a T-5, breakaway Keith needle, No. 277934). Resting flow in the LADa was measured by an electromagnetic sinewave flowmeter probe (model BL-613, Biotronex Laboratory, Kensington, Md.) that was 2, 2.5, or 3 mm in diameter according to the vessel diameter. The probe was placed at the isolation site of the LADa, at least 1 cm distal to the ligature (to avoid interference with the fit of the probe around the vessel during constriction). Flow to the LADa was controlled mechanically by a micrometer (NSK #Q01-1 series MV30, SISCO Institutional Industrial Sales, Ocala, Fla.); the micrometer screw gauge, which was sited proximal to the flowmeter probe, was used to manipulate the sling (ligature-wire) encircling the LADa. The exact location of the ligature was selected so that a 10–15-s occlusion of the LADa produced cyanosis of the cardiac apex. Teflon catheters (24 gauge) were placed into the LADa distal to the ligature, into the adjacent coronary vein (LADv), and into a distal circumflex vein (CFXv) (16). The catheters were fixed in place by using a 5-0 prolene suture placed into the epicardium adjacent to the point at which the catheter entered the vessel.

Experimental Protocol

For each animal, flow to the LADa was reduced by 50%, 75%, and 100% from resting level for 15 min each, separated by 1 h of no constriction. Thus, after 15 min of LADa constriction, the ligature was released to allow normal perfusion for 1 h, after which another 15 min of constriction to a greater degree occurred. By arbitrary assignment, adenosine (No. 1177302, Eastman Kodak Co., Rochester, N.Y.) either was infused intravenously from before the first constriction to the end of the experiment to keep Ao pressure at 50–60 mm Hg (n = 10) or was infused before constriction into the LADa distal to the constriction site at a rate titrated to maximal hyperperfusion (maximal LADa flow achieved) with <10% change from baseline of all hemodynamic variables (n = 13), or no adenosine was infused before or during constriction (n = 12, control group). Data were collected before and at the end of each LADa occlusion.

Measurements

Electrocardiogram (standard lead II) and HR were recorded continuously; cardiac output was measured in triplicate with 5 mL of 4°C injectate and a thermodilution cardiac output computer (model 9520A, Edwards Laboratories). The PA, Ao (systolic, diastolic, and mean), LV end-diastolic (post-"A"-wave), and LADa pressures and LV dP/dt (obtained electronically) were recorded continuously by using the Millar catheter (LV) or calibrated Gould-Statham P 50 transducers (LADa, PA, and Ao). Rigid, saline solution-filled polyethylene tubing (Cobe), 4 ft long, connected the PA and Ao transducers and the respective catheters. All standard transducers were calibrated with a mercury manometer and checked for drift before each measurement. The directly visualized LADa was taken as the zero reference for calibration. The flowmeter probes were calibrated before use in saline solution and then zeroed electronically and manually by constricting the vessel.

The cardiac index, stroke volume index (SVI), left ventricular stroke work index (LVSWI), and total systemic and pulmonary vascular resistances were calculated from measured variables by accepted hemodynamic formulas (17).

In all dogs, before and at the end of each LADa constriction period, blood was sampled from the Ao, PA, LADa, LADv, and CFXv for measurement of arterial blood gas tensions, pH, hemoglobin O_2 saturation (IL 282 co-oximeter, Instrumentation Laboratories, Lexington, Mass., calibrated for canine blood), and concentrations of lactate (model 27, Yellow Springs Instruments Co., Ohio), glucose (Accucheck, bG model 790, Bio Dynamics, Indianapolis, Ind.), sodium, and potassium (Lytening 1 instant ISE by AMDEV) and for calculation of base excess or deficit. Regional myocardial blood flow (RMBF) (14) was calculated for both normal and ischemic regions of the myocardium by using accepted formulas (18). For both normal and ischemic myocardium, a single transmural RMBF value was calculated from the corresponding endocardial and epicardial emission data representing approximately 6 g of myocardium.

Statistical Methods

Data from each dog were collated to allow group comparisons. Analysis of variance for repeated measure design (ANOVA PC) with post hoc testing by the Duncan test was used to determine significant variability within groups. The range of the systemic dose of adenosine was 400–600 $\mu g \cdot kg^{-1} \cdot h^{-1}$; the range of the intracoronary dose was 15–20 $\mu g \cdot kg^{-1} \cdot h^{-1}$; and the volume of adenosine infused into the LADa was 0.05–0.1 mL/min.

The control group was used to test the effect of constriction alone on the variables (that is, difference between different levels of constrictions without any adenosine). Data from groups that received adenosine were analyzed to determine the effect of the drug; therefore, data from the control and adenosine groups were compared statistically by the unpaired *t*-test with the Bonferroni correction. Frequency of occurrences was compared between groups by Fisher's exact test. The relationship of ischemic regional flow to LADa flow was determined by least-squares linear regression techniques. Alpha set at a level of <0.05 was considered significant. Results are expressed as mean ± SEM.

Results

One dog in the control group did not survive the entire experiment; two in the control group and two in the intracoronary group had a baseline coronary flow too low to allow accurate control of flow by constriction; and one in the systemic group and tw in the intracoronary group had coronary anomali that did not allow dissection or constriction accordir to the protocol. Thus, data from 8 of the 35 dogs we excluded from the analysis, and the three groups d not differ by number of dogs lost to study or t number actually studied (*n* = 9 for each group Ventricular fibrillation, which was treated by electr cal defibrillation, occurred during LADa occlusion during reperfusion in three dogs in the control grou two of which were successfully defibrillated ($P <$ 0.0 compared with adenosine groups, according to Fis er's exact test). Correlation (*r*) between LADa flo and ischemic zone RMBF in the control group w 0.87 (y-intercept of 1.65 ± 24.8). The baseline hem dynamic and metabolic data were similar for all do before any constrictions, except that HR, LV dP/d and potassium were lower in the intracoronary grou (Tables 1 and 2) (potassium in the LADv was 2.5 0.2 mEq/L compared with 3.2 ± 0.2 mEq/L wi control [$P < 0.05$]). In both adenosine groups befo constriction, flow in the LADa was higher th baseline or control (Table 2).

Effects of Coronary Constriction Alone

During each constriction of the LADa, flow (perce reduction in resting flow) and pressure decrease SVI, LVSWI, and LV dP/dt decreased; and system and pulmonary vascular resistances increased (mai ly during 100% constriction) (Table 1). During eve constriction, in coronary venous blood from the isch mic area pH was decreased, and P_{CO_2}, base deficit, a potassium and lactate concentrations increased (Ta 1). Also, in the LADa region (ischemic zone) duri constriction, delivery and consumption of O_2 and t ratio between them decreased; extraction and co sumption of lactate became significantly negative (in cating net production); and glucose extraction i creased, but not significantly (Table 1).

Systemic Effects of Adenosine

With systemic administration of adenosine befo and during each constriction, HR; Ao, LADa, a systolic LV pressures; LVSWI; LV dP/dt; and system vascular resistance decreased (Table 2). With intr coronary administration of adenosine before any co striction, only systolic LV pressure, LVSWI, and L dP/dt decreased; during constriction, only HR, A pressure, systolic LV pressure, LADa pressur LVSWI, and LV dP/dt decreased, but to a less extent than in the control group (a significant diff ence from systemic adenosine) (Table 2). Before a during constriction with systemic adenosine, SVI w significantly higher than baseline or control SVI.

LADa, left anterior descending coronary artery; SVI, stroke volume index; LVSWI, left ventricular stroke work index; LV dP/dt, LV pressure and its first derivative.

Values are mean ± SEM.

[a] $P < 0.05$ compared with before that level of constriction in the same group.

[b] $P < 0.05$ compared with baseline (not shown) in the same group.

[c] $P < 0.05$ compared with nonischemic area (not shown) at same level of contriction.

Regional Effects

Reactive hyperemia in the coronary artery was lower with adenosine, systemic or intracoronary, than without it (Table 3). Before and during constriction, resistance (LADa ratio of pressure to flow or to ischemic zone RMBF) decreased with either systemic or intracoronary adenosine (Figure 1). The calculated resistance for zone flow during 100% constriction decreased more with intracoronary adenosine than with systemic adenosine (Figure 1, bottom). With intracoronary adenosine before constriction, LADa pressure was similar to that without adenosine and similar to the baseline value for both adenosine groups, but the decrease was less than with systemic adenosine (Table 2). In both adenosine groups before constriction, flow to the LADa was higher than baseline or control. During constriction, RMBF in the nonischemic area increased with systemic adenosine and was higher than in the control group; RMBF increased in the ischemic area but did not differ significantly from control (Table 4). During constriction, ischemic zone RMBF was higher with intracoronary adenosine than in the control group, but this effect was not consistent (Table 4). During constriction with or without adenosine, the RMBF endocardial/epicardial ratio decreased in the LADa area and did not differ among the groups. During constriction, O_2 delivery, electrolytes, glucose concentration, and potassium and glucose extractions were affected similarly in the nonischemic and ischemic areas during constriction in all groups. During constriction in both adenosine groups, lactate extraction (arteriovenous [a − v] percent difference) was less negative (negative = net production) in the ischemic area compared with control values in the nonischemic area (Figure 2). Only with systemic adenosine was lactate con-

sumption ([a − v] × RMBF) less negative (Figure 2), and O_2 consumption (C[a − v]O_2 × RMBF) decreased more, which resulted in a higher delivery/consumption ratio in the ischemic area (Table 5).

Discussion

Systemic Use of Adenosine

The major finding of this study is that systemically infusing adenosine to induce hypotension during myocardial ischemia decreased O_2 demand by decreasing HR, global contractility, and systemic and pulmonary vascular pressures and resistances. Ader osine also induced redistribution of blood flow an decreased ischemic zone coronary resistance. A these effects together decreased myocardial O_2 cor sumption and lactate production in the ischemi zone. Data from the present study suggest that usin systemic adenosine to induce hypotension wi counter hemodynamic and metabolic impairmer during myocardial ischemia; these results agree wit other studies (4,19–21).

In the dog, barbiturate anesthesia can alter th baroreceptor reflex and thus lead to a high resting H (22). Therefore, decreased HR is very significant i

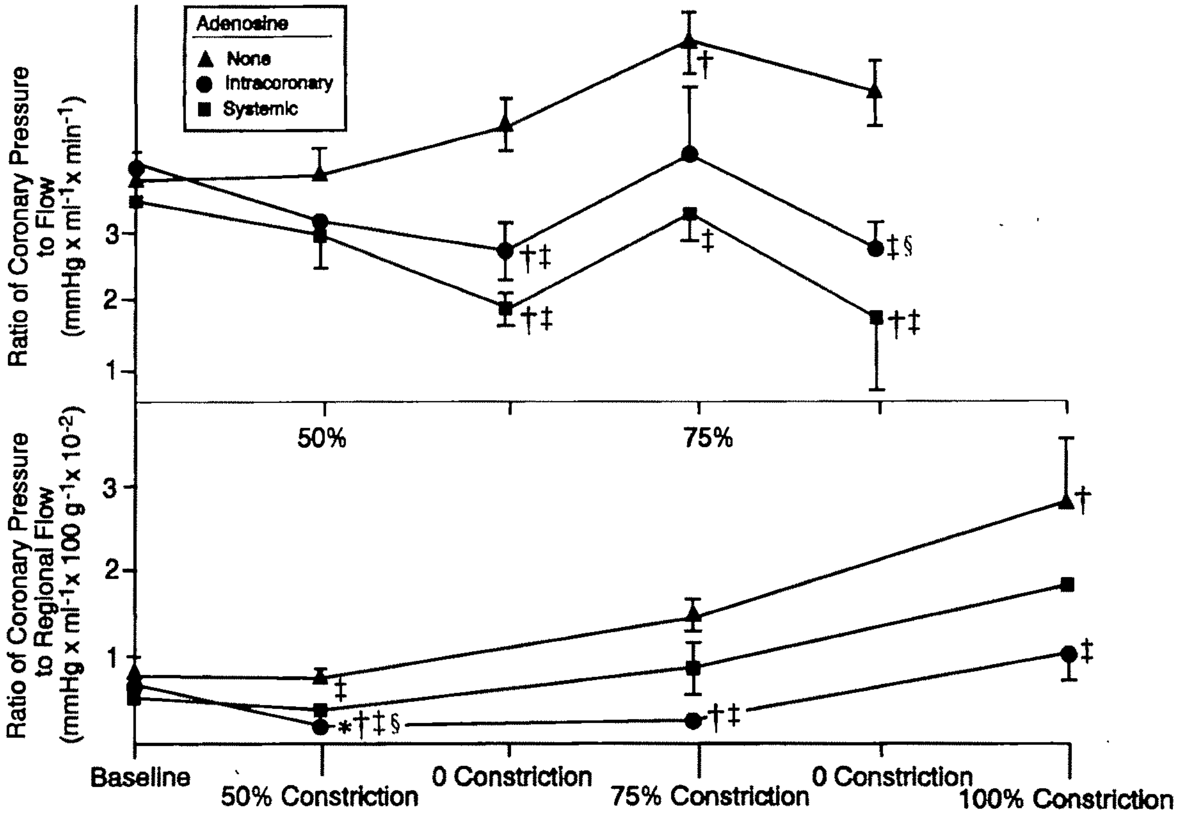

Figure 1. Coronary resistance calculated in two ways (by LADa flow [*top panel*] and RMBF [*bottom panel*]) before and during constriction of the LADa in dogs that did or did not receive adenosine. *$P < 0.05$ compared with before that level of constriction in same group; †$P < 0.05$ compared with baseline in the same group; ‡$P < 0.05$ compared with no adenosine at the same level of constriction; and §$P < 0.05$ compared with systemic adenosine at the same level of constriction.

this setting. In experiments where baseline spontaneous HR is low as that with adenosine infusion in this study, a baroreceptor may mediate a compensatory increase. In this case, O_2 consumption may increase during adenosine infusion, which may adversely affect the O_2 supply/demand ratio; however, in our present experiment, this was not the case. The significant decrease in HR that we observed with either systemic or intracoronary adenosine may have counteracted the underlying barbiturate anesthetic and potential tachycardia. If so, lower HR with a negative chronotropic agent such as adenosine is probably a significant factor in improving myocardial metabolism.

Table 4. Effects of Systemic and Intracoronary Infusions of Adenosine on Regional Myocardial Blood Flow in a Canine Model of Myocardial Ischemia

The effect of adenosine on arterial pressure also may have influenced the findings. The extent of ischemia, however, may vary inversely with arterial pressure (23); in that case, the depressor effect of adenosine (Table 2) would suppress its beneficial effect. Conversely, the decrease in Ao pressure effected by adenosine in the present study may have improved the regional myocardial O_2 delivery/consumption ratio (Table 5) by decreasing LVSWI (myocardial work), LV dP/dt (contractility), and LV pressure. The net effect of adenosine on myocardial metabolism probably depends primarily on hemodynamic variables. On the other hand, adenosine has the same potential as other metabolites produced during ischemia to have local effects on both the myocardium and the coronary vessels (10–12). Those effects are discussed later in the comparison of systemic with intracoronary effects of adenosine.

The reduction in hyperemia with adenosine reflected the decreased O_2 consumption (Tables 3 and 5). This effect may have resulted from both the initial vasodilation before constriction and from a lower need for O_2 in the myocardium (lower arterial pressure). Hyperemia may also be directly related to arterial pressure, maximal vasodilation making coronary flow completely pressure dependent.

Systemic Effect of Adenosine Compared With Its Intracoronary Effect

Without constriction, systemic adenosine induced hypotension (Ao pressure, systolic LV pressure) with bradycardia (HR), decreased contractility (LV dP/dt), and decreased systemic and coronary resistances. The peripheral effect of adenosine, however, accounted for only part of the metabolic protection because intracoronary administration with minimal peripheral effects (Table 2) still minimized to some extent metabolic impairment during coronary hypoperfusion. Both systemic and intracoronary adenosine, however, played a role in metabolic protection, considering the preserved or improved lactate extraction and O_2 delivery/consumption ratio in the ischemic zone (Table 5, Figure 2). A local metabolic effect can be expected with adenosine because of its direct effect on ATP (10,11) (reducing consumption of ATP) and its indirect effect on glucose metabolism (increasing cellular ATP) (12).

Adenosine did not increase LADa flow during constriction because the constriction was designed to decrease basal LADa flow by the same percent each time. We did find, however, significant changes in LADa flow before constriction and in RMBF measured by microspheres during constriction. Before constriction, coronary resistance was decreased with systemic or intracoronary adenosine (Figure 1, top); the decrease during constriction, however, was more apparent with intracoronary than systemic infusion (Figure 1, bottom).

The subendocardial/subepicardial perfusion ratio decreased to the same extent during constriction with or without adenosine. Therefore, maximal coronary dilation by adenosine did not change the subendocardial/subepicardial perfusion ratio according to some studies, including our data (24–26). On the other hand, submaximal doses of adenosine have preferentially dilated the subendocardium, which may result in a high subendocardial/subepicardial perfusion ratio according to one study (24), but had no effect in another study (27) and the opposite effect in an

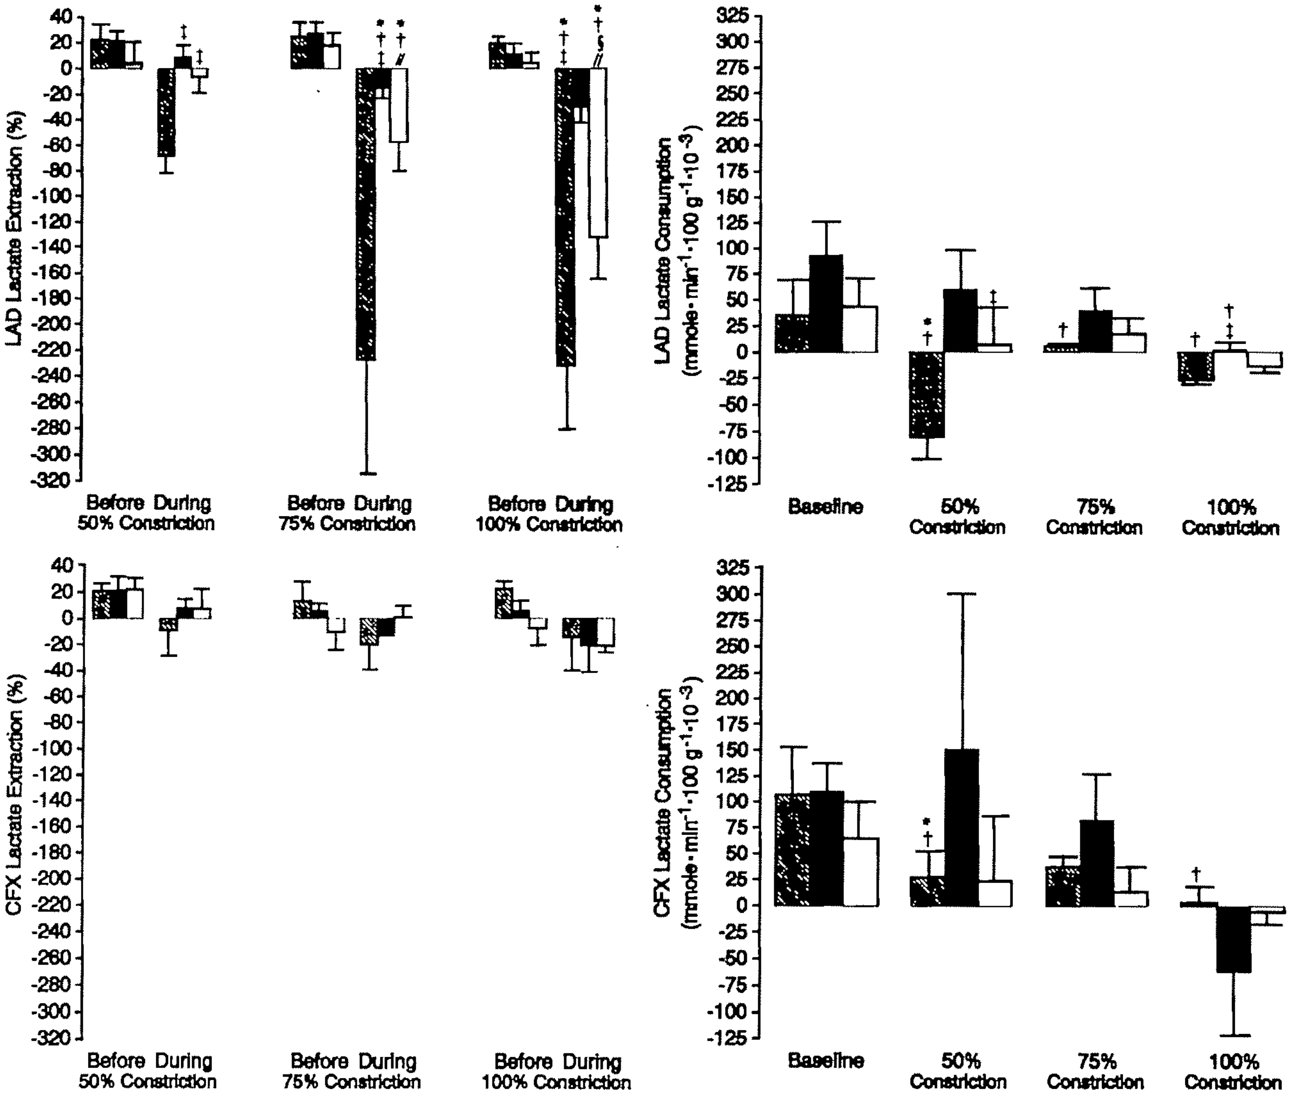

Figure 2. Effect of constriction of LADa on regional lactate metabolism in the ischemic zone (LAD) and nonischemic zone (CFX) in dogs that did or did not receive adenosine. Adenosine was administered to treatment groups at all time periods but baseline. *$P < 0.05$ compared with before that level of constriction in same group; †$P < 0.05$ compared with baseline in the same group; ‡$P < 0.05$ compared with no adenosine at the same level of constriction; §$P < 0.05$ compared with systemic adenosine at the same level of constriction; ||$P < 0.05$ compared with nonischemic area at the same level of constriction. isolated Langendorff preparation (28). These discrepant data may be related to differences in Ao pressure and HR in the various preparations (29) and in our study (30) to various factors, such as the different experimental design (single stenosis as opposed to multistenotic) and the different amount of adenosine.

We could not demonstrate steal, even though with intracoronary adenosine only distribution of flow was increased in the ischemic region, and in the nonischemic region with systemic adenosine in this model. To document steal, the LADa should be totally constricted, and the circumflex arterial flow must be reduced. Therefore, this is not a good model of steal.

Experimental Ischemic Model

Several aspects of the experimental model used in this study require consideration. The flow probe was used only as a guide to constriction, not to correlate flow values with RMBF. Technical problems, however, with the false-positive effect of constriction are possible. In the control group, LADa flow correlated closely with ischemic zone RMBF ($r = 0.87$; y-intercept 1.65). Thus, apparently the position of the ligature relative to the probe did not affect measurements of flow despite potential collapse of the vessel during constriction. Next, dogs usually have substantial cor-

[d] $P < 0.05$ compared with systemic adenosine at the same level of constriction.

onary collateral circulation and normal collateral vessels; we isolated a single coronary artery only to create ischemia, which differs from the clinical situation in which multiple coronary lesions of various lengths and degrees of stenosis are often present. Deleterious effects observed in this model are likely to be amplified in humans; on the other hand, the beneficial effects related to the substantial collateral blood flow in the dogs might not occur in humans who do not have the chronic coronary constriction that would create collateral channels.

Given the usually substantial flow network in canine myocardium, it may seem unreasonable to consider the LADa and CFXv samples obtained during LADa constriction as representative of totally ischemic and totally normal myocardium, respectively. Even during adenosine infusion, lactate concentration increased slightly, and lactate extraction became negative (significantly less than in the ischemic zone, but this still indicates lactate production or spillout) in the nonischemic (CFXv) region. Because the amount of this production (Figure 2) did not differ significantly from before constriction but did differ significantly from that in the ischemic zone (LADa), this probably indicates some contamination of those venous samples with blood from the ischemic area (14,15). Overall, arterial blood gas and metabolic changes differed markedly between the LADa and the CFXv perfusion areas during LADa constriction (Table 1, Figure 2), which indicates a severely ischemic state in the LADa perfusion area.

Calculation of lactate output and production in the ischemic region was done in two different ways (Figure 2): lacate extraction (percent change [a − v]), which is the conventional means, and lactate consumption ([a − v] × RMBF). The consumption calculation takes into account flow to the area as well as (a − v) lactate difference, whereas lacate extraction does not take blood flow into account. A difference between these two forms of calculation could have been related to the actual change in blood flow to the ischemic area. When flow decreases, evacuation of lactate decreases, and that increases the measured lactate concentration (millimoles per liter) in venous samples from the ischemic area (30). In fact, lactate extraction failed to differ distinctly between systemic and intracoronary adenosine, but lactate consumption did (Figure 2). Similar calculations that took blood flow into the ischemic region into consideration (Table 5) were done for regional O_2 delivery and consumption. Clearly, quantifying the degree of anaerobic metabolism requires calculation of the actual mass of O_2 used and lacate produced, not just the arteriovenous O_2 content difference and lactate (a − v) percent change.

To conclude, our study does indicate that systemic use of adenosine during moderate-to-severe coronary constriction and resultant hypoperfusion could mitigate myocardial ischemia. Clinical trials of adenosine for vasodilation and for inducing hypotension are needed. Intracoronary infusion of adenosine did not provide as much metabolic protection as systemic adenosine. The local effect on myocardial performance and regional myocardial blood flow is beneficial but is only partially responsible for improved metabolic outcome during ischemia. The effect of adenosine on peripheral hemodynamics, which is associated with decreased myocardial afterload, must combine with the local effect of adenosine to achieve a maximal therapeutic effect.

Patients scheduled for vascular surgery are considered at risk for perioperative cardiac complications. Choice of anesthetic in such patients is guided by a desire not to adversely affect myocardial function. On the basis of data from laboratory studies, thoracic epidural anesthesia (TEA) has been advocated to prevent myocardial ischemia. The aim of this study was to assess whether TEA combined with general anesthesia has any effect on segmental wall motion (SWM) monitored by transesophageal echocardiography in these patients. Patients received alfentanil, midazolam, vecuronium, and 50% N_2O in oxygen, and ventilation was controlled after orotracheal intubation; 12.5 mL of 2% lidocaine HCl was injected through an epidural catheter placed at T6-7 or T7-8. Hemodynamic measurements and transesophageal echocardiographic recordings were obtained before and 10, 20, 30, 40, and 60 min after lidocaine injection. Segmental wall motion was graded a posteriori by two independent experts on a predetermined scale (from 1 = normal to 5 = dyskinesia). A decrease ≥2 grades was considered an SWM abnormality indicative of ischemia. Thoracic epidural anesthesia induced a decrease in systemic arterial blood pressure, heart rate, and cardiac index. The SWM score decreased slightly from 1.34 ± 0.68 to 1.27 ± 0.64 (mean ± SD) (at 10 and 20 min, respectively) ($P < 0.05$). Patients were a posteriori analyzed according to whether they had documented coronary artery disease or not. The SWM score before TEA was significantly higher in patients with documented coronary artery disease (1.51 ± 0.88 vs 1.17 ± 0.51, respectively; $P < 0.05$) and did not change significantly after TEA. A small but statistical decrease in the SWM score was documented in the other patients (1.08 ± 0.27 at 40 min). Ephedrine was injected intravenously in two patients because of systemic hypotension >30%. In these two patients, ephedrine induced reversible SWM abnormalities that may be related to ischemia. Thoracic epidural anesthesia combined with general anesthesia did not worsen or improve SWM in patients at risk for myocardial ischemia; however, correction of hypotension with ephedrine may induce ischemia in these patients.

(Anesth Analg 1992;75:329–35)

Coronary artery disease (CAD) is common in patients undergoing vascular surgery (1). Because cardiac complications are the major cause of perioperative morbidity (2) and myocardial infarction is the most common cause of postoperative mortality in these patients (3), anesthetic technique is an important issue.

Use of a combined technique of epidural anesthesia plus general anesthesia for aortic vascular surgery remains controversial (4,5). A combined technique can increase perioperative intravascular fluid requ ments; may be more likely to result in signific hypotension with release of the aortic cross-clam the patient has an inadequate intravascular fl volume; takes extra time to initiate; and may exp the patient to the additional risk of two anesth techniques, particularily if the epidural block is formed at the thoracic level (5).

In contrast, numerous studies have demonstra a beneficial effect of thoracic epidural anesth (TEA) on the heart and coronary circulation (6– Indices of both myocardial oxygen supply and mand are decreased by TEA, and coronary perfus remains matched to myocardial O_2 consumption spite decreased mean arterial blood pressure (M and coronary perfusion pressure (6–11). Thor epidural anesthesia reverses ST segment chan

induced by experimental coronary artery occlusion and, in dogs, reduces the anatomic extent of experimentally induced infarcts (6,7). In patients with unstable angina pectoris, TEA can relieve chest pain (8) and increase lumen diameters of stenotic coronary arteries without increasing diameters of nonstenotic arteries (10). These studies may explain the earlier results of Reiz et al. (12) who demonstrated less intraoperative myocardial ischemia (measured by ST segment depression, myocardial lactate extraction, myocardial hypoxanthine production, and cardiac dysrythmias) and lower reinfarction rates in patients with recent myocardial infarction (<3 mo) who underwent predominantly iliac or abdominal aortic surgical procedures under a combined technique of general anesthesia plus low or mid-TEA, respectively, compared with a randomized group receiving general anesthesia alone (12). Thus, there may be beneficial reasons to combine TEA, which blocks the cardiac sympathetic fibers, with general anesthesia in patients with CAD undergoing surgical procedures associated with significant perioperative cardiac morbidity.

Segmental wall motion (SWM) and wall-thickening abnormalities are sensitive and early indices of myocardial ischemia (13,14), and transesophageal echocardiography (TEE) easily detects these changes. Moreover, TEE is better than electrocardiographic (ECG) and capillary pulmonary artery pressure monitoring for early detection of ischemic events (13). On the other hand, the accuracy of TEE is influenced by changes in afterload.

Other than the Reiz et al. (12) study, all of the studies demonstrating beneficial cardiac effects of TEA were performed either in animals or in humans receiving TEA alone and usually limited to T1-5 (6–10,15,16). Obviously, a combined technique has different hemodynamic and cardiac effects. Because the Reiz et al. (12) results have not been confirmed by other investigators, we decided to investigate the effect of TEA plus general anesthesia on SWM in patients scheduled for aortic vascular surgery.

Methods

After approval of the Ethical Committee of Hôpital Henri Mondor, Université Paris XII, we studied 26 consecutive patients scheduled for major vascular surgery (abdominal aortic aneurysmectomy) under TEA associated with general anesthesia. Patients with symptoms of congestive heart failure who had either a cardiothoracic ratio >0.55 on chest radiograph or a radionuclide angiographic ejection fraction <40% and those receiving inotropic drugs during the protocol were excluded from the study. The diagnosis of CAD was documented preoperatively if at least one of the following was present: (a) a history of angina pectoris; (b) documented previous myocardial infarction; (c) dipyridamole thallium scintigraphy demonstrating hypofixation with or without redistribution of the isotope; or (d) coronary angiography showing a critical stenosis >75% in at least one main coronary vessel.

All patients were premedicated with oral flunitrazepam (1.0 mg) and received their usual cardiovascular medication 1 h before the study began. On arrival in the operating room, a 16-gauge catheter was inserted into a peripheral vein for intravenous colloid infusion. A 20-gauge radial artery catheter was inserted under local anesthesia for continuous monitoring of arterial blood pressure and blood sampling for plasma lidocaine and catecholamine measurements. An epidural catheter was inserted into the epidural space through an 18-gauge Tuohy needle at the T6-7 or T7-8 interspace. A pulmonary artery catheter was introduced through the right internal jugular vein. An ECG lead (CM_5) was placed for heart rate monitoring and detection of ischemic events (Hewlett Packard 5000 monitor, Palo Alto, Calif.). Patients were considered to have ischemia when ST segment depression >1 mm for >1 min occurred. Anesthesia was induced with alfentanil (15 μg/kg IV) and midazolam (0.15 mg/kg IV). Tracheal intubation was facilitated by vecuronium (0.1 mg/kg). Anesthesia was maintained with 50% nitrous oxide in oxygen, and a continuous intravenous infusion of midazolam ($0.15\ mg \cdot kg^{-1} \cdot h^{-1}$) throughout the study period and surgery. After induction of anesthesia, a 5-MHz probe (Vingmed) of two-dimensional TEE was inserted to obtain a short-axis view of the left ventricle at the mid-papillary muscle level. This view is characterized by the circular shape of the left ventricle cavity with the posteromedial papillary muscle imaged at the 11-o'clock position and the anterolateral papillary muscle at the 7-o'clock position. The TEE was monitored continuously during the study. Videotape recordings for 5-min periods were made at regular intervals simultaneously with hemodynamic measurements (before and 10, 20, 30, 40, and 60 min after TEA).

The study began 30 min after induction of general anesthesia to ensure a stable hemodynamic baseline. The following measurements were performed: systolic, mean, and diastolic arterial blood pressures; pulmonary artery occluding pressure (PAOP); systolic, diastolic, and mean pulmonary arterial pressures; cardiac output; and systemic arterial and mixed venous blood gases for calculation of arterial and venous oxygen content and difference. Hemodynamic measurements were performed at six predetermined intervals: before and 10, 20, 30, 40, and 60 min after thoracic epidural injection of 12.5 mL of 2.0%

lidocaine HCl. The TEE short-axis views were recorded at the same time over periods of 2 min each for a posterior wall motion evaluation (Panasonic AG6200).

We measured arterial plasma lidocaine concentrations with an immunofluorescence technique (Abbott TDX) at the same time as hemodynamic measurements. The intra- and interassay coefficients of variation for lidocaine dosage were 5%. Simultaneously, arterial blood samples were collected in chilled, heparinized tubes and immediately centrifuged at 4°C for 10 min for plasma catecholamine (epinephrine and norepinephrine) measurements. The plasma was stored at −80°C until assay. Plasma epinephrine and norepinephrine concentrations were calculated twice for each sample using a double-isotope radioenzymatic assay with intra- and interassay coefficients of variation of 8% and 12%, respectively (17).

A colloid infusion (Plasmion) was administered at a rate of 10 mL/kg over a 40-min period beginning 10 min before the epidural injection of lidocaine to maintain a constant PAOP. When MAP decreased >30% below the preanesthetic values, an ephedrine (3–9 mg IV) bolus dose was administered. After the study had been completed, surgery was performed with the same anesthetic technique and monitoring.

The TEE data of each patient were analyzed on two separate occasions by two independent experts unaware of the patient's condition and hemodynamic profile during the study. The left ventricle was divided arbitrarily into four segments for SWM analysis: anterior, posterior, inferior, and septal. The SWM was scored (13) using the following grading system: 1 = normal wall (good thickening and >30% segment shortening); 2 = mild hypokinesia (slightly reduced thickening and 10%–30% segment shortening); 3 = severe hypokinesia (<10% segment shortening and minimal thickening); 4 = akinesia (no thickening and no segment shortening); and 5 = dyskinesia (wall thinning). A decrease ≥2 grades was considered indicative of ischemia. Interobserver discrepancies defined as a SWM evaluation ≥1 grade difference were resolved by a third experienced expert as a consensus.

Hemodynamic, left ventricular SWM, and plasma lidocaine and catecholamine data were analyzed using analysis of variance for repeated measures and a modified paired and unpaired Student's *t*-test; $P < 0.05$ was considered significant. Data are expressed as mean ± SD.

Results

No complications resulted from TEE probe insertion or use or from any other monitoring or anesthetic technique. Two patients were analyzed separately for SWM and hemodynamic variables after they had received intravenous ephedrine for treatment of hypotensive episodes occurring 10 and 40 min after lidocaine injection (MAP 50 mm Hg in each case). The reason for this was that ephedrine induced changes in SWM and in hemodynamics different from those observed under TEA.

Twenty-two men and two women were analyzed together. Mean patient age was 65 ± 8 yr, mean weight was 69 ± 12 kg, and mean height 170 ± 8 cm. Thirteen patients had hypertension, and 15 were receiving chronic cardiac medication (Table 1). Eleven of the 24 patients had CAD documented preoperatively (Table 1).

Norepinephrine, but not epinephrine, plasma levels significantly decreased at all measurement times after lidocaine epidural injection (Table 2). Plasma lidocaine values never reached toxic range (Table 2).

Hemodynamic data are reported in Table 3. A significant decrease in heart rate, MAP, cardiac index (CI), and estimated coronary artery perfusion pressure occurred at all measurement times after TEA. A small but statistically significant increase in PAOP occurred at 20, 40, and 60 min after TEA.

Transesophageal echocardiography revealed 23 SWM abnormalities in 11 patients before epidural lidocaine injection that were located predominantly in the inferior (38%) and septal (29%) wall segments. After epidural anesthesia, SWM abnormalities improved by 1 grade in 9 of these 23 segments and worsened in none. Four new SWM abnormalities (SWM score worsening from 1 to 2) were observed after TEA, two of which returned to baseline by the next study period 10 min later. The mean SWM scores revealed a small but statistically significant decrease after TEA (Table 3).

The subgroup hemodynamic data and SWM scores in patients with (CAD group) and without previously documented CAD (NCAD group) (Table 1) were analyzed and compared a posteriori. Baseline hemodynamics did not differ significantly between the two groups (Table 4). The hemodynamic change induced by TEA differed only slightly between the groups. Heart rate, MAP, and coronary perfusion pressure decreased in both groups, but CI decreased only in the CAD group. The PAOP remained stable in the CAD group but increased significantly (from 7 to 9 mm Hg) at 20, 40, and 60 min after TEA in the NCAD group.

The baseline mean SWM score was significantly less in the NCAD group compared with the CAD group (1.17 ± 0.51 vs 1.51 ± 0.88, respectively; $P < 0.05$). The mean SWM score did not change after TEA in patients with CAD but showed a small but statistically significant decrease in the NCAD group. Before TEA, there were 10 SWM abnormalities in four patients in the NCAD group and 13 SWM abnormal-

ities in seven patients in the CAD group. These SWM abnormalities improved in three and six patients, respectively; two new SWM abnormalities occurred in each group.

There was no interobserver variability ≥2 grades with regard to SWM analysis. The overall interobserver correlation for SWM grading was 96%. A third observer resolved disagreements of 1 grade difference in SWM score in 12 cases. The SWM could not be analyzed in 12 of the 552 total segments available for analysis.

Two patients who documented an important decrease (>30%) in systemic MAP received ephedrine. The SWM was analyzed but the results were considered separately. In both cases, although SWM was judged normal before and after epidural anesthesia when the hypotension occurred, intravenous ephedrine injection was followed by abnormalities in the inferior and septal segments, graded 4 and 5, respectively. One of these patients demonstrated ST segment depression (ECG lead CM_5) after ephedrine injection when systemic MAP increased from 50 to 65 mm Hg and heart rate from 40 to 90 beats/min. In the other patient, ephedrine increased MAP from 50 to 60 mm Hg and heart rate from 90 to 106 beats/min. Abnormalities in SWM resolved within a few minutes without treatment when heart rate returned to values documented before ephedrine injection. These two patients had an uneventful perioperative course, with no change in postoperative ECG or increase in creatine kinase-MB documented postoperatively.

Discussion

In agreement with previous studies (11,12), we observed that the combination of TEA plus general

anesthesia decreased MAP, heart rate, CI, and estimated coronary perfusion pressure, but PAOP remained nearly constant owing to colloid infusion. The decrease in CI might be explained by a decreased inotropic effect of TEA related to thoracic sympathetic blockade (6,11,15). Despite the large decrease in estimated coronary perfusion pressure, TEA plus general anesthesia did not worsen SWM or induce myocardial ischemia, even in patients with documented CAD, suggesting that oxygen supply remained equal to oxygen consumption. Coronary artery blood flow is usually maintained during systemic arterial hypotension due to coronary artery vasodilation but can be limited by coronary stenosis where maximal vasodilation occurs only in downstream vessels. Coronary vessel adaptation should have been enhanced by TEA, which has been documented to vasodilate stenosed epicardial coronary arteries (10). Because TEA decreases left ventricular stroke work and increases the diastolic time of coronary perfusion due to the decreased heart rate, this should improve the myocardial oxygen supply/demand ratio. In addition, the decrease in myocardial contractility might have decreased the intramyocardial tissue pressure and the corresponding vascular resistances (18).

In a previous study (19), we demonstrated that lumbar epidural anesthesia induced SWM changes indicative of myocardial ischemia. Discrepancies between our two studies might be explained by the previously described beneficial effects of cardiac sympathetic blockade (7–10) that occur with TEA but not with lumbar epidural blockade. In one case (lumbar epidural blockade), the decrease in systemic arterial pressure and consequently the decrease in coronary artery perfusion pressure may lead to a decrease in coronary artery blood flow, which compromises the myocardial oxygen supply. In the other case (TEA), the decrease in cardiac work and in myocardial oxygen demand may compensate for the decrease in coronary artery blood flow. Any increase in cardiac work may nevertheless lead to myocardial ischemia, as illustrated by the two patients who received ephedrine.

Ephedrine, which has both α- and β-adrenergic properties, increases both heart rate and arterial blood pressure, thus increasing oxygen consumption and reducing oxygen supply by a decrease in diastolic time (20). The changes in SWM observed in the two patients treated with ephedrine suggest that significant hypotension during TEA was well tolerated and perhaps preferable to pharmacologic manipulations aimed at increasing coronary perfusion pressure when no TEE or ECG evidence of myocardial ischemia is present.

Detection of ischemia with TEE does have some limitations. We monitored the wall motion activity at the short-axis view of the left ventricle at the midpapillary muscle level. Although perfusion beds of the three main coronary arteries are usually imaged at this level (21), basal and apical wall motion abnormalities could be missed. Although two-dimensional TEE is a reliable technique for detecting SWM abnormalities (13), it is difficult to quantify wall thickening and endocardial wall motion. To determine wall thickening requires powerful software and measures not possible in real time. Our estimates of wall thickening were therefore qualitative. Measuring endocardial wall motion requires a reference axis. During systole, the center of mass of the left ventricle changes by translation and rotation. Use of either a floating or fixed axis permits analysis but can result in under- or overestimation of the extent of abnormal wall motion (14); however, there is no consensus on the optimal centroid for evaluation of wall motion (14,22). We limited this problem by using the papillary muscles as reference points. Overestimation may occur because of "tethering" (i.e., segments of the myocardium adjacent to ischemic or infarcted segments may display contraction abnormalities related to proximity to the affected segments) (21,23–26). Nevertheless, this effect concerns only 5% of the myocardial circumference (27).

Changes in left ventricular loading conditions result in changes in SWM scores. A decrease in preload or afterload could make normal segments appear hyperkinetic such that abnormal segments would be overgraded. Conversely, ischemic walls might appear to decrease their function when preload or afterload is increased. In this study, preload (estimated by PAOP) remained constant, but afterload decreased, which might have artifactually improved SWM scores.

Hypokinesia may be less specific than dyskinesia or akinesia in detecting myocardial ischemia (28). Although we chose hypokinesia in this study as a threshold for ischemia to increase the sensitivity of the technique, there were no SWM changes indicative of myocardial ischemia. Finally, this study compares SWM after TEA to a control state that follows anesthetic induction. The actual preanesthetic SWM scores by TEE are not available. General anesthesia alone might have induced the SWM abnormalities not reversed by the subsequent epidural anesthesia. Preoperative TEE could address this question, but insertion of the esophageal probe in awake patients is stressful and may induce SWM changes.

We conclude that patients undergoing major vascular surgical procedures are prone to develop myocardial ischemia (29–32). Our study adds further support to the body of information demonstrating a beneficial effect of TEA in patients with CAD; we showed that TEA does not change SWM in these patients despite a significant decrease in estimated coronary perfusion pressure. Correction of hypotension induced by TEA must be monitored carefully because myocardial ischemia related to the increased oxygen demand may occur.

Role of Systemic Arterial Pressure, Heart Rate, and Derived Variables in Prediction of Severity of Myocardial Ischemia During Acute Coronary Occlusion in Anesthetized Dogs

Peter G. Moore, MB, PhD, John A. Reitan, MD, Nguyen D. Kien, PhD, David A. White, MD, and Amira M. Safwat, MD

Department of Anesthesiology, School of Medicine, University of California, Davis, California

The present study examined the postulate that the quotient of mean systemic arterial pressure and heart rate predicts the severity of myocardial ischemia during occlusion of the left anterior descending coronary artery. Studies were performed in open-chest fentanyl-anesthetized dogs before and during halothane ($n = 8$) or isoflurane ($n = 8$) anesthesia. The pressure-rate quotient (PRQ) decreased significantly in both groups during incremental increases in halothane or isoflurane to 68% and 57% of control values at 0.5 MAC and to 41% and 38% at 1.5 MAC for halothane and isoflurane, respectively. Myocardial lactate production was unchanged from the ischemic region, and no correlation between the PRQ and myocardial lactate production was observed. In contrast, heart rate correlated significantly ($r = 0.376$; $P < 0.05$) with lactate production. The product of systolic systemic arterial pressure and heart rate (rate-pressure product) correlated with blood flow ($r = 0.493$; $P < 0.001$) and with oxygen consumption ($r = 0.571$; $P < 0.001$) in the normal myocardium. A weak correlation ($r = 0.330$; $P < 0.05$) of rate-pressure product with myocardial lactate production from the ischemic region was observed. There were no correlations between the PRQ and myocardial lactate production from the ischemic region or indices of blood flow distribution (i.e., inner/outer ratio in the ischemic region or ischemic/normal ratio). The relationship of hemodynamic variables to measurements of regional myocardial metabolism was independent of background anesthetic agent or depth of anesthesia. The current data suggest that heart rate changes are weakly predictive of severity of myocardial ischemia. No interdependence between heart rate and blood pressure on blood flow regulation to ischemic myocardium is evident. The findings indicate that the PRQ has limited prognostic value in the assessment of severity of myocardial ischemia under laboratory conditions.

(Anesth Analg 1992;75:336–44)

Although there is a growing awareness that myocardial ischemia often occurs in the absence of hemodynamic change (1,2), control of heart rate and systemic arterial pressure endures as the sine qua non of safe anesthesia in patients with coronary artery disease (3). Recent laboratory reports (4,5) reinforce this principle and attempt to quantitate the relative contribution of heart rate and blood pressure to changes in myocardial oxygen balance. These studies suggest that the quotient of mean arterial pressure and heart rate (PRQ) provides an "effective" prediction of severity of myocardial ischemia (4,5). In a canine model dependent on nutrient flow through ischemic collateral vessels (4), both collateral/normal and inner/outer flow ratios in the ischemic region correlated significantly ($r = 0.61$ and 0.78, respectively) with the PRQ. Significant but less precise correlations with the elements of the PRQ (i.e., heart rate [HR] and mean arterial pressure) were also described (4). Similar findings were reported in an animal model wherein ischemia was induced by critical stenosis of a coronary artery (5) and worsening ischemia was denoted by systolic wall thickening of the ischemic region. In view of these findings, the authors (4,5) suggest the potential usefulness of the PRQ as a prognostic indicator of myocardial ischemia in humans.

This laboratory previously found no evidence for worsening of myocardial ischemia with halothane or isoflurane during acute coronary occlusion (6). The aim of the present study, in contrast to other reports (4,5), was to characterize HR and systemic arterial

pressure relationships with respect to regional oxygen supply and demand during more severe ischemia evoked through acute coronary artery occlusion. Direct measurements of regional oxygen supply and demand and regional metabolism were obtained in a canine model in which HR and systemic arterial pressure were free to vary. A secondary aim was to determine the effectiveness of the PRQ as a predictor of myocardial ischemia in the presence of either halothane or isoflurane anesthesia.

Methods

The study was approved by the Institutional Committee for Animal Use and Care of the University of California, Davis, and conducted in accordance with its guidelines.

Animal Preparation

Sixteen mixed-breed male and female dogs weighing 22.9 ± 0.7 kg (mean ± SEM) were used in the experiments. Anesthesia was induced with thiamylal (15 mg/kg), the trachea intubated, and ventilation established with a positive-pressure Harvard respirator. Anesthesia was maintained with nitrous oxide in oxygen and by fentanyl (100 μg/kg IV), followed by a continuous infusion of fentanyl (1–2 $\mu g \cdot kg^{-1} \cdot min^{-1}$); ventilation and fraction of inspired oxygen were adjusted to maintain normoxia and normocapnia. Sodium bicarbonate was given before the study period if base deficit exceeded 5 mEq/L; this was not repeated during the protocol. A semirigid catheter was inserted into the thoracic aorta by means of a femoral arteriotomy for reference blood sampling and aortic pressure measurements. Cardiac output was measured via a pulmonary artery flow-directed catheter by the thermodilution technique using iced saline solution and an Edwards computer (model 9520A, Santa Ana, Calif.); values were averaged from intermittent triplicate measurements.

A left thoracotomy at the fifth intercostal space was performed using aseptic surgical techniques; the pericardium was opened, and a flexible polyethylene catheter was inserted into the left atrium for pressure measurement and injection of radioactive microspheres. Left ventricular (LV) pressure was measured by a Konigsberg micromanometer (model P7, Pasadena, Calif.) inserted through a stab wound in the apex of the ventricle and secured with a pursestring suture. The Konigsberg transducer was calibrated in vitro with a mercury manometer and in vivo with aortic systolic and left atrial pressures. Frequent calibrations were made to eliminate the electrical drift of the transducer. Arterial blood pressure was measured with Statham pressure transducers (model 23dB, Hato Rey, Puerto Rico). A pulsed Doppler flow transducer was placed around the left anterior descending coronary artery (LAD) near its origin, and a ligature snare for future use was placed around the same artery just proximal to its first marginal branch; the flow transducer was used to determine zero flow. After heparinization, two small epicardial veins on the left ventricle in the region of the LAD draining the region distal to the snare and a region outside the distribution of the LAD were cannulated for blood sampling; free drainage of each catheter was allowed.

Arterial and coronary venous samples were collected anaerobically for the measurement of oxygen saturation (IL Co-oximeter 282, Lexington, Mass.) and blood lactate concentrations (YSI 2300 Stat, Yellow Springs Instruments, Yellow Springs, Ohio); incomplete data were obtained in four dogs owing to venous catheter occlusion. Calculation of regional myocardial extraction ratios, production, and consumption for oxygen and lactate were made from arteriovenous concentration differences and regional myocardial blood flow measurements with a modified Fick equation. Body temperature was maintained at >37°C with a heating pad. Hemodynamic data were recorded on a direct writing polygraph (model 2800S, Gould, Cleveland, Ohio) and on an analogue FM tape recorder (Kyowa Electronic Instruments, Tokyo, Japan) for subsequent analysis.

Physiologic Measurements

Variables, including systemic arterial pressures, HR, and cardiac output were measured, and stroke volume, systemic vascular resistance, and pulmonary vascular resistance were calculated with standard formulas. Coronary perfusion pressure was calculated from the difference between diastolic aortic pressure and the LV end-diastolic pressure. The rate-pressure product (RPP) was calculated from the systolic systemic arterial pressure multiplied by the HR and the pressure-rate quotient (PRQ) by the division of mean systemic arterial pressure by HR (4).

Regional blood flow was measured with radioactive microspheres, as previously described (7). In brief, approximately 2–3 × 10^6 microspheres (15 μm) labeled with ^{95}Nb, ^{46}Sc, ^{141}Ce, or ^{85}Sr were injected into the left atrium over 20 s. A reference blood sample was withdrawn from an arterial catheter starting 15 s before the microsphere injection and continuing for 2 min at a constant rate of 7.75 mL/min. The order of the isotopes was randomized. After the experiment was completed, the animal was killed with an intravenous injection of saturated KCl. The sampled organs were then removed, sectioned,

weighed, and counted for radioactivity. The LV ischemic region was identified by an intracoronary injection of 0.3 mL of methylene blue at the site of occlusion and a sample was taken with margins >1 cm. Regional blood flow was calculated from the ratio of radioactive count of measured sample and that of reference blood sample.

Experimental Protocol

A period of 1 h was allowed to elapse after instrumentation; nitrous oxide was replaced by nitrogen and ventilation and oxygenation were set to provide normocapnia and normoxia. End-tidal gases were measured throughout the experiment with a Medspect mass spectrometer (AIMT, St. Louis, Mo.).

After baseline measurements were obtained, LAD occlusion was achieved by closure of the ligature snare. Postocclusion hemodynamic variables, myocardial blood flow, and metabolic indices (i.e., oxygen and lactate balance) were measured after 30 min. Dogs were randomized to receive either halothane or isoflurane, and anesthetic concentrations within each agent were administered in randomized order. Steady-state comparisons were made at equianesthetic dosages at low (halothane 0.4%, isoflurane 0.6%) and high (halothane 1.2%, isoflurane 1.8%) alveolar concentrations. Measurements were repeated at each stage of the experiment under stable end-tidal anesthetic gas concentrations.

Data Analysis

Data were compared within and between anesthetic groups at each experimental stage using repeated measures analysis of variance and analysis of covariance, with a significance level set at 0.05. In addition, correlation coefficients were compared for each data set (no volatile agent, halothane, or isoflurane). When no significant differences were detected among data sets, the results were combined to yield a single correlation coefficient value to examine the association between hemodynamic variables and invasive measurements of regional myocardial oxygen supply/demand balance.

Results

Changes in core temperature, hemoglobin values, arterial blood gases, and acid-base status during the course of the experiment are shown in Table 1. The preparation showed good stability, apart from a small decrease in hemoglobin concentrations with time.

There were no significant changes in baseline hemodynamic variables after acute LAD occlusion (Table 2). After LAD occlusion, total myocardial blood flow (MBF) in normally perfused myocardium was 95 ± 5 $mL \cdot min^{-1} \cdot 100\ g^{-1}$ tissue, whereas MBF in the ischemic region was 38 ± 6 $mL \cdot min^{-1} \cdot 100\ g^{-1}$ tissue ($P < 0.001$, compared with the normal region). The inner/outer blood flow ratio in the ischemic region was 0.69 ± 0.08 compared with baseline values of 0.96 ± 0.06 ($P < 0.001$) in the normal myocardium. There were no significant changes in HR, systolic arterial pressure (SAP), diastolic arterial pressure (DAP), mean arterial pressure (MAP), RPP, or PRQ after LAD occlusion (Table 3). Myocardial oxygen extraction from the ischemic region increased significantly in all dogs (Table 3) after LAD occlusion. No evidence of LV failure was apparent according to cardiac output and LV end-diastolic pressure measurements.

With the introduction of a volatile agent, the RPP was not significantly changed at 0.5 MAC values for both agents but decreased at 1.5 MAC to 70% ($P < 0.05$) and 72% ($P < 0.05$) of control values for halothane and isoflurane, respectively

Table 2. Hemodynamic Variables Before and After Acute Left Anterior Descending Coronary Artery Occlusion in 16 Fentanyl-Anesthetized Dogs

Variable	Before occlusion	After occlusion
Heart rate (beats/min)	73.3 ± 6.5	84.4 ± 6.4
Cardiac output (L/min)	2.54 ± 0.15	2.58 ± 0.15
Mean systemic arterial pressure (mm Hg)	95.3 ± 3.7	92.1 ± 5.0

Left ventricular end-diastolic pressure (mm Hg)	6.78 ± 0.97	6.88 ± 0.81
Coronary perfusion pressure (mm Hg)	65.1 ± 3.6	65.0 ± 3.9
Systemic vascular resistance (dynes·s·cm^{-5})	2957 ± 198	2868 ± 265
Pulmonary vascular resistance (dynes·s·cm^{-5})	250 ± 28	240 ± 29

Results are presented as mean ± SEM.

(Figure 1). Concomitant decreases in myocardial oxygen consumption ($M\dot{V}O_2$) from normal myocardium at 1.5 MAC to 64% ($P < 0.05$) and 64% ($P < 0.05$) of control values were observed for halothane and isoflurane, respectively (Figure 1). There were significant correlations ($r = 0.571$; $P < 0.001$) between RPP and $M\dot{V}O_2$ (Figure 2) and between RPP and MBF ($r = 0.493$; $P < 0.001$) for the grouped data (Table 4).

The PRQ decreased significantly with the introduction of volatile anesthetics, decreasing to 68% ($P < 0.05$) and 41% ($P < 0.05$) at 0.5 and 1.5 MAC halothane, respectively, and to 57% ($P < 0.05$) and 38% ($P < 0.05$) at 0.5 and 1.5 MAC isoflurane, respectively (Figure 3). There was no significant correlation between PRQ and the ratio of ischemic/normal flow for either agent (Figure 3). Myocardial lactate production from ischemic myocardium was unchanged (Figure 4).

Individual hemodynamic variables were subjected to multiple correlation analysis to determine their relationship with indices of myocardial oxygen supply and demand. There were no significant differences in correlation coefficients among baseline, halothane, or isoflurane groups for the comparisons, and data for each group were combined to yield a single correlation coefficient for each comparison between hemodynamic variable and measures of MBF and metabolism (Table 4).

In the normally perfused region of the left ventricle, SAP ($r = 0.398$; $P < 0.05$), DAP ($r = 0.355$; $P < 0.05$), MAP ($r = 0.394$; $P < 0.05$), and RPP ($r = 0.493$; $P < 0.001$), but not PRQ ($r = 0.198$; P = NS), revealed significant correlations (Table 4) with regional transmural MBF. Significant correlations of SAP ($r = 0.518$; $P < 0.001$), DAP ($r = 0.531$; $P < 0.001$), MAP ($r = 0.551$; $P < 0.001$), RPP ($r = 0.571$; $P < 0.001$), and PRQ ($r = 0.338$; $P < 0.05$), but not HR ($r = 0.061$; P = NS), were observed with $M\dot{V}O_2$ from the normal region.

In ischemic myocardium, correlation coefficients were weak but reached significance for SAP ($r = 0.362$; $P < 0.05$) and MAP ($r = 0.316$; $P < 0.05$), but not DAP, HR, RPP, or PRQ, when correlation analysis with regional transmural MBF was performed (Table 4). There was also a weak association between $M\dot{V}O_2$ from the ischemic region and SAP ($r = 0.389$; $P < 0.05$), DAP ($r = 0.321$; $P < 0.05$), and MAP ($r = 0.367$; $P < 0.05$). The ratio of inner/outer flow in the ischemic region was not associated with any HR or blood pressure variable (Table 4). Myocardial lactate production from the ischemic region showed significant positive correlations for HR ($r = 0.376$; $P < 0.05$) and RPP ($r = 0.330$; $P < 0.05$). The PRQ did not correlate with any measured index of severity of myocardial ischemia.

Independent measures of myocardial regional oxygen supply and demand (MBF, $M\dot{V}O_2$, and myocardial lactate production) in the ischemic region showed no association with the volatile agent used (namely, halothane or isoflurane) or with end-tidal concentrations of the agent.

Discussion

The present data reinforce the concept that the complex interactions that regulate blood flow to normal and ischemic myocardium defy simple description by noninvasive variables such as HR and systemic arterial pressure (8,9). For example, although rate and arterial blood pressure show weak correlations with oxygen supply and demand in normal myocardium, their predictive value in relation to quantification of ischemic flow is poor when they are free to vary. This is not surprising, because the PRQ and RPP encompass only two of the many inputs regulating regional MBF (8–10).

Blood Flow Distribution and Metabolic Effects During Acute Ischemia

It has been successfully argued that HR effects are paramount in either determining the degree of myocardial ischemia or precipitating ischemia during anesthesia (11,12). An increase in HR induces a concomitant increase in blood flow to normal myocardium to match increased metabolic demand, the latter mechanism mediated through the release of local vasodilator factors such as adenosine (13,14). By contrast, it is assumed that in the ischemic bed,

vasodilator reserve is largely exhausted, and therefore the increased metabolic work associated with HR increases cannot be matched by significant increases in flow, thus exacerbating the existing supply-demand imbalance (11,12,15–18). In the present analysis, higher HRs were associated, albeit not strongly, with increased lactate production from the ischemic region.

Several authors (5,16,19,20) have stated that in view of the reliance of ischemic myocardium on collateral flow for oxygen supply, coronary perfusion pressure to the collateral bed becomes critically important to the maintenance of adequate blood flow. In the present study, there were weak associations between systemic pressures and regional MBF and oxygen consumption in the ischemic bed. Yet, in the range of values observed in the present analysis and in our concurrent study (6), there was no adverse redistribution of blood flow from the ischemic region despite a wide range of coronary perfusion pressures (6) submitted to analysis. These data support the postulate that in the canine model, even with acute coronary occlusion, modest vasodilator reserve persists in ischemic myocardium, possibly reflecting the extensive collateralization in the dog. This mechanism (21) can, for the most part, assist in the maintenance of perfusion to the ischemic area, provided that perfusion pressure to the collateral bed remains in the autoregulatory range (22). For example, it is suggested that myocardium may adapt to ischemia by downregulating its energy requirement

below blood flow-limited rates of energy production (23,24).

Systemic hypertension is also thought to have an adverse impact on myocardial oxygen balance (16,20,25) through increases in myocardial work, which if not matched by increased blood flow to the heart, can lead to worsening ischemia. In the present analysis, this was not found to be a major factor, pointing once again to the previous hypothesis. Of note, in relation to the previous discussion, it has been shown that local vasodilator component mechanisms are restrained during ischemia through neural vasoconstrictor activation (10,26,27). Paradoxically, this response counters the tendency toward transmural steal in the ischemic region (10). Whether disturbances of neurally mediated vasoconstriction play a role in modifying blood flow distribution to ischemic myocardium during halothane or isoflurane anesthesia is a question that remains open to future study.

Limitations of the Present Analysis

Factors regulating blood flow to ischemic myocardium are primarily dependent on factors controlling blood flow to adjacent normal myocardium through collateral beds (8,28) and on local biochemical and mechanical changes affecting vascular tone in the ischemic region (8,28). In the present study, ischemia was evoked through occlusion of the LAD. Therefore, collateral flow hinges on anatomic connections with adjacent myocardium, which in the dog, in contrast to humans, tend to be plentiful but nonetheless do not provide as reliable a safety margin as collateral vessels formed through slow, progressive ischemia. In addition, native collateral vessels are believed to have less vascular reactivity than collateral vessels formed through chronic ischemia (29,30) and may therefore be less likely to respond to a vasodilator stimulus (8). For example, any diminished responsiveness of abruptly opened collateral channels could contribute to our failure to observe any deleterious blood flow redistribution phenomena. Nevertheless, this argument is opposed by studies in similar models (31,32) demonstrating that redistribution of blood away from an ischemic region can be elicited when a powerful local vasodilator stimulus is applied.

In the ischemic region, transmural and inner/outer flow measurements showed considerable variability to LAD occlusion. This was unlikely to be due to an error of tissue sampling, because care was taken to leave wide margins around the sample taken from the ischemic zone. The variability is more likely to be due to between-dog variability in anatomy with respect to collateral flow dependence and problems inherent in using an animal model with native collateral vessels rather than those formed by ischemia. The average flows obtained from the ischemic region are consistent with values obtained by other researchers using similar animal models (31–36).

As mentioned, although there is considerable variability among dogs in response to coronary occlusion, blood flow persists through collateral vessels to the ischemic region, independent of complex changes in hemodynamic variables. This implies that despite conditions that are traditionally thought to induce redistribution of blood flow away from ischemic myocardium through vasodilation of adjacent normal myocardium, there appears to be adequate vasodilator reserve (9) to maintain flow to match myocardial oxygen consumption in the ischemic region. Presumably, provided that coronary perfusion pressure to the collateral bed is maintained above a critical value, even under acute hypoperfusion evoked by coronary occlusion, collateral flow can be further augmented in response to changes in myocardial oxygen demand (i.e., because of inherent collateral vessels, occlusive ischemia is a graded phenomenon and not an absolute ablation of blood flow).

Nevertheless, one consideration that has to be raised in the current investigation is the possibility that infarction may have occurred in some dogs in response to occlusion, and therefore the findings might not be relevant to acute ischemia. Although this possibility cannot be excluded, continuing maximal oxygen extraction and persistent and stable oxygen consumption by the ischemic region indicate that at least some degree of contractile function and functional integrity remained intact, presumably supported by collateral flow. Under these circumstances, the fundamental principles governing collateral flow (8) to the functioning ischemic myocardium should continue to apply.

Comparison With Other Studies

Our findings differ considerably from other studies (4,5) that found a reasonably good correlation between PRQ and collateral/normal and ischemic inner/outer flow ratios during regional hypoperfusion. However, there were a number of major differences between the studies that could account for the disparities. In particular, Buffington et al. (4) induced ischemia over a period of days with an Ameroid constrictor mounted on a coronary artery to induce collateral vessel formation. Therefore, resting collateral flow was greater than that observed in the present study. In relation to the comparison of PRQ with myocardial flow variables, a further divergence resided in their study protocol in which HR was controlled by atrial pacing at rates >96 beats/min (4). In contrast, in the present experiments HR was free to vary and, despite a wide range of values, more than half were <90 beats/min (i.e., the analysis contained more values in the physiologic range normally observed under anesthesia). In animals with higher HRs, higher myocardial oxygen consumption will be observed, possibly leading to greater susceptibility to small reductions in regional myocardial perfusion; whereas in the present analysis, lower HRs may confer a greater margin of safety before adverse changes in ischemic metabolism, such as an increased lactate production, are evident. In the clinical environment, for the quotient to hold any predictive value in determination of myocardial ischemia, it should hold true throughout the normal physiologic range observed in humans under general anesthesia (37,38).

Implications of the Present Analysis

In view of the restrictions applied by Buffington et al. (4), and on the evidence of the present study, the PRQ fails to adequately predict the severity of myocardial ischemia under laboratory conditions when HR, arterial pressure, and myocardial contractility are free to vary. The present data add weight to recent reports (39,40) concerning patients undergoing coronary artery bypass surgery that showed a poor association between hemodynamic correlates and the incidence of myocardial ischemia evidenced by regional wall motion abnormalities.

Although the PRQ has been shown to have little predictive value in the present setting, this does not diminish the importance of control of HR and arterial blood pressure in patients with coronary artery disease (41). The present findings uphold to a limited extent the traditional view that HR increases can be associated with worsening ischemia (1–3). The data also point to the complex interactions that summate to determine regional MBF (8) and the potential of other mechanisms, possibly local or neural (10), to influence myocardial oxygen supply. Heart rate control (3,42), coincident with maintenance of an adequate coronary perfusion pressure (3), remains important to the conservation of blood flow during severe hypoperfusion; however, more research is needed to gain an understanding of mechanisms of ischemia unrelated to hemodynamic events (39).

The authors greatly appreciate the work of Lynn Gall in the preparation of the manuscript and the technical assistance provided by Richard Martucci, Darcy Quam, and Collette LaRocque during the conduct of the experiment.

Should All Children With Suspected or Confirmed Malignant Hyperthermia Susceptibility Be Admitted After Surgery? A 10-Year Review

Steven M. Yentis, FCAnaes, Mark F. Levine, MBBCh, and Elizabeth J. Hartley, FRCPC
Department of Anaesthesia, The Hospital for Sick Children, University of Toronto, Ontario, Canada

Children otherwise suitable for same-day discharge may be admitted to the hospital solely because they are known or suspected to be malignant hyperthermia-susceptible (MHS). To determine whether their hospitalization is necessary, the medical charts of 303 children labeled MHS who had undergone surgery with anesthesia free of malignant hyperthermia-triggering agents on 431 occasions between 1981 and 1990 were reviewed. Eighteen of these patients (25 cases) who were subsequently identified as biopsy-negative were excluded from the study. We recorded the reason for the MHS label and the perioperative management and outcome of the cases. Fifty-eight percent of procedures were followed by hospital admission solely because of the patient's MHS label. None of the 25 children (33 cases) with biopsy-proven malignant hyperthermia developed intraoperative or postoperative pyrexia. Ten children suspected to be MHS developed pyrexia >38.5°C. These episodes were not considered to be malignant hyperthermia and were not treated with dantrolene. None of the remaining 275 patients exhibited any features of malignant hyperthermia, although one had an adverse reaction to radiologic contrast medium. On the basis of our retrospective analysis, postoperative admission to the hospital solely on the basis of the MHS label is not warranted.

(Anesth Analg 1992;75:345–50)

The label malignant hyperthermia-susceptible (MHS) is conferred after positive muscle biopsy (1). Although many more children are suspected to be MHS because of a family history of malignant hyperthermia (MH) or a previous suspected MH reaction, the incidence of true MHS within this group of children is unknown.

Management of all MHS patients at our hospital, The Hospital for Sick Children, Toronto, Ontario (HSC), has consisted of administering an anesthetic free of MH-triggering agents, followed by monitoring for 4 h in the recovery room and overnight on the ward. The patients are observed for increases in temperature and other features of MH. The surgery itself, however, may not always warrant overnight admission to the hospital. Disadvantages of overnight stay include disruption to the patient and his or her family, increased risk of infection, and increased health care cost (2).

An informal telephone survey of the anesthesia departments of six major North American children's hospitals revealed that all six allow certain suspected MHS children to go home after minor surgery. Although anesthesia without complications has been reported in adults (3–5) and children (6) undergoing muscle biopsy for MH, there is less information available for the effects of anesthesia for other types of surgery in suspected or proven MHS patients (7) and none specifically for children. In particular, the policy of same-day discharge for these children has not been assessed. We therefore retrospectively reviewed the history, management, and outcome of all suspected or proven MHS patients who presented for surgery within a 10-yr period to ascertain the incidence of intraoperative and postoperative complications.

Methods

Malignant hyperthermia-susceptible patients were identified from the following sources at HSC: Health Records' diagnosis database, Patient Operative Care Unit's surgical and Dentistry's booking lists, and Department of Anaesthesia's consultation and muscle biopsy records. From the 303 charts of MHS-proven or MHS-suspected patients who underwent

431 surgical procedures at HSC over a 10-yr period between January 1, 1981, and December 3, 1990, the following information was recorded for each patient: age, gender, date and nature of the surgery, use of prophylactic dantrolene, and duration of anesthesia.

The reasons for the MHS label were also recorded: positive muscle biopsy, previous suspected MH reaction, previous masseter muscle rigidity (MMR), and first-, second-, or more distant, degree relative with a history of suspected MH reaction or positive muscle biopsy. Eighteen (25 procedures) of the 303 patients recorded as suspected MHS were excluded because of subsequent negative muscle biopsies. During our 10-yr study period, patients with a history of MMR were given the MHS label and were therefore included in our analysis. If MMR was associated with acidosis or other signs of MH, we considered it an MH reaction.

The dates and test centers of muscle biopsies and details of suspected MMR and MH reactions in the children and their relatives were recorded when available. Most biopsies performed in our patients and their relatives were analyzed at Toronto General Hospital (TGH) where, since 1987, 3% halothane has been used in the caffeine halothane contracture (CHC) test, in accordance with the North American Malignant Hyperthermia protocol (8). Before this, a less specific test with 1% halothane was used (9). Variations in test procedures may result in center-to-center differences in specificities (9).

Also noted were axillary temperatures >38.5°C that occurred intraoperatively or postoperatively (within 3 days of surgery) and complications (defined as other adverse events possibly related to MH, such as cyanosis, arterial desaturation, hypercapnia, tachypnea, tachycardia, or muscle rigidity identified as such in the nursing or medical records, irrespective of other causes or whether treatment was required.

Results

Of the 285 patients (406 procedures) included in the study, 168 were male and 117 female. They ranged in age from 2 mo to 19 yr.

Figure 1 illustrates the number of surgical procedures performed and the proportion of patients eligible for same-day discharge. The surgical procedures performed included 39% ear, nose, and throat surgery; 19% dental surgery; 11% orthopedic surgery; 9% general surgery; and 7% urologic procedures. Same-day discharge would have been feasible in 231 (57%) of the 406 cases if not for the MHS label (Figure 1).

All patients received anesthetics free of MH-triggering agents. Duration of anesthesia ranged from 15 min to 6.7 h.

Prophylactic dantrolene (0.5–1.5 mg/kg) was administered to all suspected MHS patients treated before 1985 (10). In addition, 10 children received dantrolene intravenously from 1987 to 1988 during a pharmacokinetics research study (11).

Table 1 summarizes the reasons recorded for the MHS label. Of these 285 patients, 25 (33 procedures) had biopsy-proven MH. Ten patients (15 procedures) had biopsy specimens analyzed at TGH before 1987, and 13 (16 procedures) had their biopsy specimens analyzed at TGH after 1987. Two patients had biopsies performed at other centers.

Information about the acquisition of the suspected MHS label for the remaining 260 patients was frequently incomplete. This was due in part to the retrospective nature of the study: documentation was often poor, and parents or patients lacked information about biopsies or reactions occurring in relatives or at other hospitals. A history of a previous MH reaction was the reason for the suspected MHS label in 23 patients undergoing 36 procedures. Sixteen of these patients had their suspected MH reactions at other institutions. These reactions were most commonly associated with an unexplained rise in temperature and sometimes elevated creatine kinase (CK) levels, acidosis, or admission to an intensive care unit. Of the seven patients who had their previous suspected MH reactions at our hospital, two had MMR accompanied by acidosis, and five had an unexplained rise in temperature accompanied by acidosis.

Masseter muscle rigidity was the reason for the suspected MHS label in 11 patients (13 procedures): 3 patients at other institutions and 8 at our institution. The CK levels were measured postoperatively in five of our patients and did not increase to >6000 U/L in any patient.

Two hundred twenty-six patients (324 procedures) acquired the MHS label because of a relative's positive biopsy or history of a previous MH reaction. Frequently, details were lacking because of incomplete documentation by the anesthetist or the patient's or parents' inadequate knowledge about the details. The most common reason for a child to be suspected MHS was to have a first-degree relative with biopsy-proven MH (63 relatives). The majority of these biopsies (41 relatives) were performed at TGH before 1987. Details about previous MH reactions in first-degree relatives were often inadequate; however, an unexplained rise in temperature was the most frequent presenting sign. Chart information about more distant relatives was frequently vague. Parents may have been aware of a relative's MH reaction or a positive muscle biopsy but knew no other details, or they were not documented.

There were no cases of intraoperative pyrexia

Reason for MHS label	Patients (n = 285)	Procedures (n = 406)
Biopsy-positive	25	33
Previous MH reaction	23	36
Previous masseter spasm	11	13
First-degree relative, biopsy-positive	63	100
First-degree relative, previous MH reaction	23	27
Second-degree relative, biopsy-positive	57	79
Second-degree relative, previous MH reaction	24	28
More distant relative, MH reaction or biopsy-positive	59	90

MHS, malignant hyperthermia-susceptible; MH, malignant hyperthermia.

(>38.5°C) in 285 suspected or known MHS patients in our study. None of the 25 biopsy-proven MH patients developed postoperative pyrexia or other signs of an MH reaction. Six of these 25 children had received routine preoperative dantrolene.

Ten (3.5%) of the 285 suspected MHS patients developed postoperative pyrexia (Table 2). Four of these patients had received routine prophylactic dantrolene. An anesthetist examined all 10: in five the fever was due to a cause other than MH; in the remaining five a cause was not determined, but the fever was not thought to be part of an MH reaction and settled after administration of acetaminophen, without sequelae. Of the 10 patients who developed postoperative fever, three had surgical procedures not requiring postoperative admission. Although the fever responded to acetaminophen in all three subjects, these children may have required readmission had they been sent home.

Intraoperative dantrolene was given to a 7-yr-old patient when the pulse rate increased from 160 to 200 beats/min, arterial oxygen saturation decreased from 92% to 89%, and temperature increased to 38.4°C after an injection of radiologic contrast medium during cardiac catheterization. There was no muscle rigidity; end-tidal partial pressure of carbon dioxide did not increase; and postoperative CK was normal. The patient was subsequently thought to have suf-

Table 2. Details of Malignant Hyperthermia-Susceptible Patients With Postoperative Pyrexia >38.5°C

Pt No.	Age	Reason for MHS label	Length of surgery (min)	Comments
1	5 mo	Second-degree relative, clinical diagnosis	Club-foot repair (140)	T-39.0°C 13 h postoperatively, treated with acetaminophen; RR, PR, and BP were 36–40 breaths/min, 140–180 beats/min, and 96–110 mm Hg, respectively, compared with preoperative values of 40–50 breaths/min, 130–140 beats/min, and 90–110 mm Hg, respectively
2	2 yr	Cousin, clinical diagnosis	Ptosis repair (100)	BP 195 mm Hg after 10 min of anesthesia (PR 170 beats/min). T <37.0°C intraoperatively, P_{ETCO_2} <40 mm Hg during IPPV, no rigidity. Postoperatively, BP remained 100–110 mm Hg, PR 90–120 beats/min and RR 20–30 breaths/min; T = 38.8°C at 3 and 9 h, settling on both occasions after oral acetaminophen
3	3 yr	Second-degree relative, positive biopsy	Nephrectomy for Wilm's tumor (240)	T-39.0°C at 2.5 h, associated with radiologic and clinical evidence of atelectasis; arterial blood gas analysis revealed no acidosis or hypercapnia
4	5 yr	Uncle, positive biopsy	Adenotonsillectomy (30)	T-39.0°C at 5.5 h and 38.9°C at 16 h; treated with acetaminophen. RR, PR, and BP were unchanged (20–22 breaths/min, 120–130 beats/min, and 100–118 mm Hg, respectively)
5	5 yr	Cousin, clinical diagnosis	Bronchoscopy after TEF repair (60)	T-38.8°C at 4 h, associated with radiologic and clinical evidence of atelectasis. Prophylactic dantrolene had been administered
6	5 yr	Second-degree relative, clinical diagnosis	Orchidopexy (65)	T-38.0°C at 6 h, 40.5°C at 8 h, and 38.0°C at 11 h, settling each time with acetaminophen. Arterial blood gas analysis revealed normal parameters; RR, PR, and PB were unchanged (22–30 breaths/min, 120–130 beats/min, and 110–120 mm Hg, respectively)
7	6 yr	Cousin, clinical diagnosis	Dental restoration (210)	T-38.9°C at 6 h. Clinical evidence of otitis media. RR, PR, and BP were unchanged (18–26 breaths/min, 104–130 beats/min, and 90–100 mm Hg, respectively). Prophylactic dantrolene had been administered
8	8 yr	First-degree relative, clinical diagnosis	Debridement of leg wound (150)	T-38.6°C at 4 h, treated with acetaminophen. Had persistent wound infections. RR, PR, and BP were unchanged (20–24 breaths/min, 90–120 beats/min, and 100–110 mm Hg, respectively)
9	9 yr	Previous MH reaction	Spinal fusion (205)	T-38.7°C at 19 h, treated with acetaminophen. RR, PR, and BP were unchanged (24–28 breaths/min, 110–130 beats/min, and 100–120 mm Hg, respectively). Prophylactic dantrolene had been administered
10	14 yr	First-degree relative, biopsy-positive	Spinal fusion (360)	T-39.0°C at 36 h, associated with radiologic and clinical evidence of atelectasis. Arterial blood gas analysis revealed normal acid-base parameters and carbon dioxide tension. Prophylactic dantrolene had been administered

fered an adverse reaction to the contrast medium rather than to have had an MH reaction (12).

A 4-yr-old boy labeled MHS who had suffered a massive head injury required general anesthesia for craniotomy and died 2 days later without regaining consciousness. He exhibited no sign of MH throughout his hospital admission.

Discussion

In the past, overnight hospitalization of suspected or confirmed MHS patients after surgery has been a common practice, even after minor surgery. Previous to this review, these patients were admitted postoperatively for overnight monitoring at HSC. During our 10-yr study period, more than half the patients admitted postoperatively would have been eligible for same-day discharge if not for their MHS label. From the results of this large retrospective study, hospitalization of suspected or muscle-biopsy-proven MHS patients who have undergone uncomplicated surgery is not necessary.

None of the children with biopsy-proven MH in our study developed postoperative pyrexia or signs of MH after administration of nontriggering anesthesia. Postoperative pyrexia occurred in 10 (3.5%) suspected MHS patients. None of these children had an MH reaction nor were they given dantrolene. Postoperative pyrexia may have necessitated readmission of the three children who had outpatient-type procedures if they had been sent home on the day of surgery. All episodes of pyrexia responded to treatment with acetaminophen. Isolated pyrexia has been shown to be a poor predictor of MH in children (6); postoperative pyrexia is common in non-MHS children (13–15).

Postoperative MH reactions are rare after administration of anesthesia free of MH-triggering agents (5). Grinberg et al. (16) presented three cases of mild MH reactions developing in adult patients after trigger-free anesthetics. The reactions were diagnosed on the basis of pyrexia, moderate hypertension, mild metabolic acidosis, and slight hypercapnia. The longest interval between the completion of anesthesia and pyrexia was 5.5 h. Other factors, including a lack of postoperative analgesia, may have been involved. There have been no reports of severe MH reactions after trigger-free anesthesia. The period of risk after surgery of short duration with a trigger-free anesthetic technique is not known. After triggering anesthetics, most cases of postoperative MH have occurred within 1 h postoperatively (17–19), although one MH reaction was reported to have occurred 11 h after exposure to halothane (20). Recurrence after initial recovery from a fulminant MH reaction may occur >30 h postoperatively if dantrolene has not been given (21). The number of suspected MHS patients who have MH is unknown. Until an easy, reliable MH-susceptibility test is available, we will continue to use an MH protocol for suspected MHS children undergoing surgery.

Our findings suggest that intraoperative and postoperative complications are rare in patients labeled as MHS who undergo even prolonged surgery with trigger-free anesthesia. These are consistent with the findings of Hackl et al. (7) who reported a small postoperative increase in temperature and CK after 30 general anesthetic procedures in 24 biopsy-positive patients undergoing miscellaneous surgery with no other complications. As both this study and ours were retrospective, some complications may have been unrecorded in the patients' charts and thus missed. In addition, some MHS patients may have escaped inclusion in our survey. The number of confirmed MHS (as opposed to suspected MHS) patients is small (25 patients undergoing 33 procedures); however, our results suggest that the policy of admission of all MHS patients, regardless of the type of surgery they have undergone, may represent an unnecessary burden on health care resources. We conclude that same-day discharge for suspected or biopsy-proven MHS patients after uncomplicated ambulatory surgery is safe. A small number of these children may require readmission if a fever develops after discharge. A prospective study is now under way to investigate same-day discharge in children labeled MHS.

We are grateful to Dr. J. Lerman for his helpful comments in preparing this article. This article was prepared with the assistance of Medical Publications, the Hospital for Sick Children, Toronto, Ontario.

Metoclopramide Reduces the Incidence of Vomiting After Tonsillectomy in Children

Lynne R. Ferrari, MD, and John V. Donlon, MD

Departments of Anesthesia, Massachusetts Eye & Ear Infirmary and Harvard Medical School, Boston, Massachusetts

The efficacy of intravenous metoclopramide in controlling vomiting in children after tonsillectomy was determined in a prospective randomized, double-blind investigation. One hundred two unpremedicated, ASA physical status I or II children between the ages of 1 and 15 yr who were undergoing surgical removal of the tonsils, with or without adenoidectomy, were studied. Anesthesia was induced either with halothane, nitrous oxide, and oxygen by mask or by intravenous thiopental and was maintained with halothane, nitrous oxide, oxygen, and intravenous morphine (0.1 mg/kg). Each child randomly received either 0.15 mg/kg of metoclopramide or saline solution placebo intravenously after transfer to the postanesthesia care unit. All episodes of vomiting were recorded for 24 h after completion of surgery. The incidence of vomiting in the saline solution group was 70%, compared with 47% in the metoclopramide group ($P = 0.026$). The authors conclude that the administration of intravenous metoclopramide in a dose of 0.15 mg/kg on arrival in the postanesthesia care unit significantly decreases the incidence of vomiting in children after tonsillectomy.

(Anesth Analg 1992;75:351–4)

Tonsillectomy, one of the most frequently performed surgical procedures in pediatric patients, is often performed as an outpatient procedure in some medical centers. Although postoperative bleeding is the most serious complication, vomiting is the most frequent (1,2). Persistent vomiting and poor oral fluid intake are leading causes of unscheduled overnight admission after ambulatory surgery (2). Metoclopramide has been shown to reduce postoperative vomiting in ambulatory pediatric strabismus patients; therefore, this study was designed to determine its efficacy as an antiemetic in children undergoing tonsillectomy (3).

Methods

The study was approved by the Human Studies Committee, and written, informed consent was obtained from the parents of 102 children, ASA physical status I or II, between the ages of 1 and 15 yr undergoing tonsillectomy with or without adenoidectomy. There was no history of motion sickness or other factor predisposing to postoperative vomiting in any patient enrolled in the study. Children were randomly assigned to a postoperative intravenous medication group, either metoclopramide (0.15 mg/kg) (group A) or sterile saline solution placebo (group B). All children were unpremedicated and had not ingested solid food or milk products after midnight on the evening before surgery. Ingestion of clear liquids was permitted until 6 h before the time of surgery.

Patients were transported to the operating room accompanied by one parent, and after placement of standard monitoring consisting of automated blood pressure cuff, pulse oximeter probe, electrocardiogram, and precordial stethoscope, anesthesia was induced. Younger patients received increasing concentrations of halothane, nitrous oxide, and oxygen delivered by mask, and older patients who consented to placement of an intravenous cannula while awake received thiopental followed by inhalation of halothane, nitrous oxide, and oxygen. Endotracheal intubation was accomplished in all patients without the aid of muscle relaxant so that reversal of neuromuscular blockade could be avoided, as the use of neostigmine is associated with an increased incidence of nausea and vomiting (4). Anesthesia was maintained with inhalation of halothane, nitrous oxide, and oxygen and intravenous morphine (0.1 mg/kg). After placement of an intravenous catheter, patients received lactated Ringer's solution in a volume to restore calculated fasting fluid deficit, deliver maintenance fluid for the duration of surgery, and compensate for measured blood loss. After removal of the tonsils was completed and hemostasis achieved, the

Table 1. Clinical Characteristics of 102 Pediatric Patients Undergoing Tonsillectomy

	Saline solution (n = 51)	Metoclopramide (n = 51)
Age (yr)	6.5 ± 3.6	6.1 ± 3.4
Incidence of vomiting	70%	47%
No. of episodes of vomiting in patients who vomited	3.1 ± 2.4	1.1 ± 1.5
Time to first episode (postoperative h)	5.6 ± 2.5	6.4 ± 2.8

Results are mean ± SD.

stomach was decompressed by passing an orogastric tube under direct vision while the surgical mouth gag was still in place. After the trachea was extubated, patients were transferred to the postanesthesia care unit (PACU). Immediately on arrival at the PACU, each patient was given the coded intravenous study drug by a nurse who was unaware of the agent administered.

The time of drug administration was noted and recorded. All episodes of vomiting (nausea and retching were not included) that occurred both in the PACU and on the inpatient pediatric floor were timed and recorded by the nurse caring for the patient. No additional prophylactic antiemetic was administered. Oral fluid intake was not forced on patients, and children resumed oral intake voluntarily. The anesthesia, surgical, and nursing teams caring for these patients were unaware of the study drug given. Patients resumed oral fluid intake of their own accord. Fluids were offered and encouraged by the nursing staff; however, forced ingestion of a predetermined volume of oral fluid did not occur. All patients remained in the hospital for a minimum of 23 h and a maximum of 36 h after the completion of surgery.

The drug code was broken after all 102 investigations were completed. Statistical significance ($P < 0.05$) was determined with the Fisher exact test (two-tail), χ^2 analysis, and logistic regression.

Results

One hundred two patients were enrolled in the study, 51 patients in each group. The ages did not vary significantly between the two treatment groups. Posttonsillectomy vomiting occurred at a rate of 47% in the metoclopramide treatment group, compared with 70% in the saline solution placebo group (P = 0.026) (Table 1). In those children who did experience postoperative vomiting, the mean frequency was 1.1 ± 1.5 episodes in the metoclopramide-treated group compared with 3.1 ± 2.4 in the saline solution-treated group ($P < 0.001$) (Figure 1). Incidentally noted was the observation that patients >8 yr of age vomited less often than younger patients, regardless of treatment group. Vomiting occurred with a frequency of 29% in children >8 yr of age, compared with 68% in children <8 yr of age (P = 0.001). Alternatively, the effect of age and metoclopramide on vomiting are independent. In the younger children, <8 yr old, the metoclopramide-treated patients vomited at a rate of 53% compared with 82% in the saline solution placebo group (P = 0.014) (Table 2).

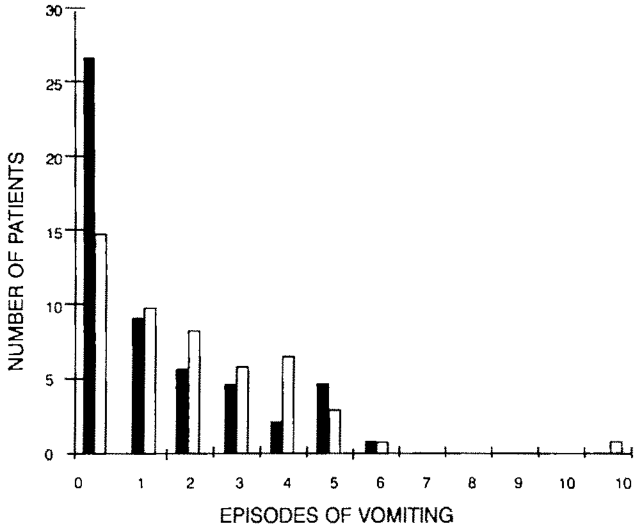

Figure 1. Frequency of postoperative vomiting in the two study groups (*solid bars*, metoclopramide; *open bars*, saline solution).

The two groups did not differ in the interval of time after surgery at which vomiting began. The first episode of vomiting occurred in the metoclopramide-treated patients at a mean of 6.4 ± 2.8 h after surgery compared with 5.6 ± 2.5 h in the placebo group ($P <$ 0.001) (Figure 2). The number of vomiting episodes occurring in the PACU and the inpatient unit did not differ between the two groups.

Discussion

The incidence of vomiting during the first 24-h period after tonsillectomy in unpremedicated children was found to be 70% in our patient population. The surgical literature reports the incidence of vomiting after tonsillectomy to range between 0.07% and 30.5% (1,2). It is difficult to determine the true incidence of vomiting in the pediatric tonsillectomy population, because studies vary in their definition of vomiting. The large discrepancy between our observations and those noted in the surgical literature is most likely due to criteria for reporting vomiting. Many authors do not include the first episode of

Table 2. Incidence of Vomiting in 102 Pediatric Patients Undergoing Tonsillectomy

vomiting, and others discount the second and third. Recurrent vomiting and poor oral fluid intake are dangerous, because they may lead to fluid depletion as well as add to the general postoperative discomfort experienced by children.

There is increasing pressure from insurance carriers to perform tonsillectomy exclusively as an outpatient procedure in an effort to stem the cost of rising health care (2). In view of this trend across the country, it is imperative that physicians caring for children search for solutions to the significant problem of postoperative vomiting and its potential for morbidity and unplanned overnight hospital admission.

Several antiemetic agents have been used postoperatively in children and studied, but none has been without significant undesirable effects. Intravenous droperidol in the effective dose of 0.075 mg/kg has been reported to decrease postoperative vomiting after strabismus surgery, but prolonged sedation associated with its use may delay discharge or result in unscheduled hospital admission (5,6). Other side effects associated with the use of droperidol in children include hypotension, restlessness, and extrapyramidal reactions that preclude it from routine administration (7). The use of lidocaine as an antiemetic in children has been studied, but the data on its effectiveness are conflicting and inconclusive (5,8).

Because of the effectiveness of metoclopramide in pediatric strabismus patients, the authors of this study chose to examine its effectiveness in reducing posttonsillectomy vomiting (3,9). Although the exact mechanism of posttonsillectomy vomiting is not well understood in children, anxiety, fear, or postoperative pain may play a role (10). It is known that patient gender, amount of intraoperative blood loss, performance of additional surgical procedures at the time of tonsillectomy, and surgical technique chosen are not predictive indicators of postoperative vomiting (2). We do know, however, that forcing early oral fluid intake on children after tonsillectomy does increase the risk of vomiting postoperatively (11).

The data presented in this study indicate that a difference in the incidence of vomiting between children >8 and <8 yr of age exists. The exact reason for this is not apparent, except that it is perhaps due to the older child's ability to suppress the vomiting reflex more effectively than the younger patient group. Intragastric blood either entering during the surgical procedure or postoperatively from an oozing tonsillar bed, as well as an altered gag reflex in the edematous postsurgical oropharynx, may possibly contribute to an increased stimulus to vomiting. An orogastric tube was passed intraoperatively under direct vision into the stomachs of all patients enrolled in this study in an attempt to evacuate a portion of blood and intragastric gas that may contribute to vomiting postoperatively.

The mechanism of action of metoclopramide is its ability to antagonize the inhibitory effects of dopamine on gastric smooth muscle, resulting in the forward propulsion of gastric contents. This may be uniquely beneficial in posttonsillectomy patients if in fact blood in the stomach is responsible for eliciting the vomiting reflex. Another mechanism by which the frequency of vomiting is decreased is by the action of metoclopramide in facilitating the release of acetylcholine from postganglionic nerve endings, resulting in increased lower esophageal sphincter tone.

As increased gastric emptying is not always correlated with therapeutic success, the central antiemetic effect of metoclopramide may be the most potent one. Apomorphine stimulation of dopamine receptors in the medullary chemoreceptor zone is known to result in nausea and vomiting, and metoclopramide is effective in blocking this response (12).

Although metoclopramide has been in use for a relatively short period of time, its side effects after a single dose are minimal. The marked somnolence seen with other agents is absent. Drowsiness has been reported in 10% of adult patients, but this has not been demonstrated in children. Extrapyramidal side effects have been reported in <1% of adult patients, and a study of pediatric oncology patients reported rare extrapyramidal side effects that were easily and readily reversed with the administration of diphenhydramine (3). Symptoms resembling parkinsonism have been reported in children, and these infrequent side effects are effectively treated with intramuscular diazepam (12). No side effects were noted in any patient enrolled in this investigation. It is important to note that our study provided for administration of a single prophylactic dose of metoclopramide, and this was not repeated; however, it remains to be seen whether the increased use of this drug will bring about additional reports of side effects in the pediatric population.

The dose of metoclopramide used in this study was determined by referring to data obtained in other patient populations. The dose of 0.15 mg/kg has been shown to be effective in decreasing gastric volume in healthy adult patients scheduled for elective surgery as well as those undergoing emergency procedures (13,14). In a study of prophylaxis against postoperative vomiting in pediatric strabismus patients, the lowest effective dose used was 0.15 mg/kg (3). The onset of action of intravenously administered metoclopramide is 3–5 min, and owing to the relatively short duration of action (2.4–4.6 h), it was administered immediately on arrival in the PACU to achieve the longest possible duration of action in the awake patient (3,13).

Morphine, in a uniform dose was administered to all patients to provide postoperative analgesia, even though opioids may contribute to postoperative nausea and vomiting. Morphine was chosen as the narcotic, because meperidine administration has been shown to increase the probability of vomiting in pediatric tonsillectomy patients (2).

On the basis of the results of our study, we recommend the use of intravenous metoclopramide in a dose of 0.15 mg/kg to control vomiting after tonsillectomy in children, especially those who are discharged on the day of surgery. Not only does administration of metoclopramide decrease the incidence of vomiting, but the severity is decreased when it does occur. The authors recognize that further investigation is warranted with regard to timing, dose, and administration. Perhaps a larger dose of metoclopramide may be effective in decreasing the incidence of vomiting further without increasing the incidence of significant side effects. As well, multiple dosing or drug administration preoperatively and intraoperatively may prove to be beneficial.

Comparative Effects of Laryngeal Mask Airway and Endotracheal Tube Insertion on Intraocular Pressure in Children

Mehernoor F. Watcha, MD, Paul F. White, PhD, MD, FFARACS, Lawrence Tychsen, MD, and Julia L. Stevens, MD

Departments of Anesthesiology and Ophthalmology, Washington University School of Medicine, St. Louis, Missouri

Intraocular pressure (IOP) measurements in children are frequently performed under halothane-nitrous oxide anesthesia; however, anesthesia face masks may limit access to the eyes, and tracheal intubation is associated with transient increases in IOP. Use of the laryngeal mask airway (LMA) permits the maintenance of a patent airway without the need for laryngoscopy and tracheal intubation. In a randomized study of 41 children, we compared the IOP, hemoglobin oxygen saturation, and hemodynamic responses to the insertion of an LMA or tracheal tube during a standardized steady-state anesthetic technique consisting of 1 MAC halothane and 66% nitrous oxide. Baseline measurements of IOP, hemoglobin oxygen saturation, heart rate, and arterial blood pressure were recorded and repeated within 15–30 s after insertion of the airway device and at 1-min intervals for 5 min. Insertion of the LMA required significantly less time (26 ± 16 vs 39 ± 17 s [mean ± SD]) and was associated with higher hemoglobin oxygen saturation values compared with the tracheal intubation. The LMA did not increase IOP, heart rate, or arterial blood pressure above baseline values. In contrast, tracheal intubation was associated with significant increases of IOP, heart rate, and arterial blood pressure. We concluded that the laryngeal mask offers advantages over tracheal intubation and the face mask for airway management in patients undergoing IOP measurements.

(Anesth Analg 1992;75:355–60)

Accurate, reliable intraocular pressure (IOP) measurements in children are difficult to perform without profound sedation or general anesthesia (1–3). A widely used technique involves the administration of halothane and nitrous oxide (N_2O) through a face mask; however, the anesthesiologist's attempts to maintain an adequate airway by manipulation of the jaw and face mask can occasionally interfere with the surgeon's ability to measure IOP. In addition, unrecognized pressure on the globe of the eye by the face mask may be a potential source of error. Although tracheal intubation will secure the airway and provide better conditions for the measurement, it is associated with an increase in IOP (3,4). The laryngeal mask airway (LMA) is a new device consisting of a cuff that forms a seal around the inlet of the larynx and a tube to direct gases to the larynx (Figure 1) (5–10). This method of maintaining airway control without tracheal intubation leaves the surgical field largely unobstructed and the anesthesiologist's hands free to perform other duties (5–9). However, data are not available on IOP changes when the LMA is used in children.

This prospective, randomized study was designed to compare the IOP and hemodynamic responses associated with the insertion of an LMA and an endotracheal tube in children during halothane-N_2O anesthesia.

Methods

After obtaining approval from the Washington University Human Studies Committee and written informed consent from the parents (or legal guardian) of the child, we studied 41 healthy ASA physical status I or II children scheduled for elective strabismus surgery. We excluded children <9 mo of age and <5 kg body wt, patients with poor lung compliance, those with a contraindication to the use of halothane and N_2O, and those in whom the use of the LMA would be unsuitable (e.g., children thought to have a "full stomach") (10).

Patients were asked to refrain from ingesting milk

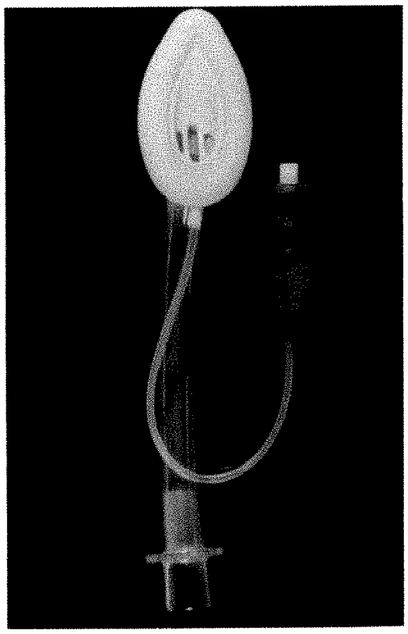

Figure 1. The pediatric laryngeal mask airway (size 2).

or solids for 6 h before induction of anesthesia but were permitted clear fluids until 2 h before the induction of anesthesia. No patient received preanesthetic medication. Anesthesia was induced in all patients with 0.5%–3% halothane and 66% N_2O in oxygen through a face mask. Inspired and expired gas samples were obtained from a catheter placed in the oropharynx and were analyzed by a mass spectrometer (Perkin-Elmer MGA 1100 mass spectrometer, Perkin-Elmer, Pomona, Calif.), calibrated with appropriate calibration gases (Scott Medical Products, Plumsteadville, Pa.). If the end-tidal nitrogen concentration exceeded 0.5%, the oropharyngeal catheter and the seal around the face mask were adjusted to exclude contamination of the sample by ambient air. Under these circumstances, the oropharyngeal samples have been shown to be representative of samples drawn from the distal end of the tracheal tube in children >6 mo of age and weighing >5 kg (11).

After loss of consciousness, the end-tidal N_2O concentration was kept constant at 66% in oxygen. In addition, all patients received halothane to maintain a constant end-tidal concentration that by itself was equivalent to 1 MAC for the patient's age (i.e., halothane end-tidal concentrations of 0.97% for 0.5–2.5 yr, 0.91% for 2.5–6 yr, and 0.87% for 7–11 yr). After vascular access was obtained, all patients received atropine (10 μg/kg) and atracurium (0.5 mg/kg) intravenously a minimum of 10 min before baseline measurements were made. The end-tidal CO_2 tension was maintained between 32 and 45 mm Hg with gentle positive pressure ventilation (peak inspiratory pressure <20 cm H_2O). Throughout the study, each patient was in the supine position, and the head was not elevated. Pressure on the eyes by the face mask was avoided at all study intervals.

After steady-state end-tidal gas concentrations for a minimal period of 10 min, baseline measurements of the IOP; heart rate (HR); systolic, diastolic, and mean arterial pressures; and hemoglobin oxygen saturation (Spo_2) were recorded. The HR, mean arterial blood pressure, temperature, and Spo_2 were measured by standard methods. The IOP was measured by one of two ophthalmologists with a Perkin's hand-held applanation tonometer after fluorescein was instilled in the conjunctival sac. Conditions for baseline and subsequent IOP measurements were evaluated by the ophthalmologist, who used a three-point scale: 1 = satisfactory, 2 = some difficulty, and 3 = unsatisfactory. During baseline IOP measurements, a Guedel oral airway was kept in place, a cushioned face mask (Vital Signs, Totowa, N.J.) was used, and the anesthesiologist's hands approached the patient's face from the side opposite to which the measurement was being made.

After baseline measurements were obtained, patients were randomized to a laryngeal mask (LMA) or an endotracheal tube (ET) group for airway maintenance. The time to insert the airway device (the time from removal of the face mask to connection of the anesthetic gas circuit to the airway device) was recorded, along with the lowest Spo_2 value during this period. Satisfactory placement of the airway device was confirmed by auscultation of the chest during gentle positive-pressure ventilation. The presence of bilateral equal breath sounds and good quality air entry excluded endobronchial intubation in the ET group and also excluded downfolding of the epiglottis over the laryngeal inlet with consequent airway obstruction in the LMA group.

The IOP and hemodynamic values were measured within 15–30 s of the insertion of the airway device and at 1-min intervals thereafter for 5 min, along with the Spo_2 values. After the airway was secured, patients continued to receive positive-pressure ventilation as previously described. After the study was completed, the choice of the airway device used during the strabismus correction surgery was left to the discretion of the attending anesthesiologist.

For purposes of statistical analysis, the IOP data were divided into sets relating to the left eye and the right eye, respectively, and separate analyses were performed with each data set. The IOP, Spo_2, and hemodynamic values after insertion of the airway device were compared with the preinsertion values by a one-factor analysis of variance for repeated measures, with separate evaluations for each airway management group. If the null hypothesis was re-

After airway device inserted	76[b]	75[b]

LMA, laryngeal mask airway; ET, endotracheal tube; Spo_2, oxygen saturation; IOP, intraocular pressure.
Mean ± SD.
[a] $P < 0.05$ vs LMA group.
[b] $P < 0.05$ vs preinsertion value.

jected, a Student-Newman-Keuls test was used for post hoc comparisons. At each time point of measurement, the IOP, Spo_2, and hemodynamic values between the two airway management groups were compared by an analysis of variance and by an unpaired Student's t-test, with Bonferroni corrections for multiple comparisons. A Wilcoxon signed rank test was used to compare conditions during baseline IOP measurements (when a face mask was used) with subsequent measurements made after the airway was secured. Where appropriate, Fisher's exact test or χ^2 tests with Yates' correction were used. A P value <0.05 was considered statistically significant. Values are presented as mean ± SD unless otherwise stated.

Results

There were no significant differences between the two groups in age, weight, gender, ASA physical status, or in the end-tidal gas concentrations at which the study was performed (Table 1). Because there were no significant differences in the IOP values between the two eyes of the same patient at any time in the analysis, we have arbitrarily chosen to present IOP values for the right eye only. This was the first eye in which IOP was measured at each time point. There were also no significant differences between the two groups in the baseline IOP, hemodynamic, or Spo_2 values.

Endobronchial intubation or downfolding of the epiglottis was not detected in any patient in the ET or LMA group, respectively. The time taken to insert a tracheal tube was significantly greater than the time taken to insert the LMA. The Spo_2 values immediately after the insertion of the airway device were significantly lower in the ET group compared with the LMA group (Table 2). However, after reinstitution of positive-pressure ventilation, there were no significant differences in the Spo_2 values between the two airway management groups.

Immediately after insertion of the airway device, there was a significant increase in IOP over baseline values in the ET group but not in the LMA group (Figure 2). During the entire study, IOP values in the LMA group were not significantly different from baseline values. In contrast, IOP values in the ET group remained significantly higher than baseline values (and higher than the corresponding values in the LMA group) for 2 min after tracheal intubation. By 3 min, there were no significant differences between the IOP values in the two groups or between the time-related IOP value and the baseline value in each of the two treatment groups (Figure 2).

Acute hemodynamic changes accompanied the changes in the IOP (Figure 2). Immediately after tracheal intubation there was a significant increase in HR and systolic, diastolic, and mean arterial pressures above baseline values and the corresponding values in the LMA group. In the ET group, HR remained significantly higher than baseline values for 4 min after tracheal intubation, whereas systolic, diastolic, and mean arterial blood pressures returned to baseline values in 3, 2, and 3 min, respectively. In contrast, there were no significant differences in HR, systolic, diastolic, and mean arterial pressures compared with baseline values in the LMA group (Figure 2).

Conditions for baseline and subsequent IOP measurements did not differ between the two airway management groups at any time point. However, satisfactory conditions were reported less often during baseline measurements when a face mask was

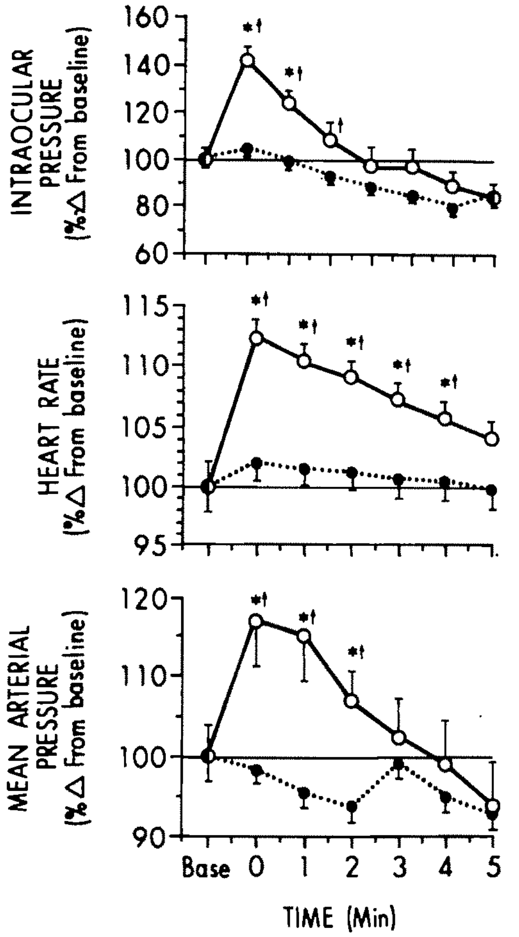

Figure 2. Comparison of the percent changes (%Δ) in intraocular pressure, heart rate, and mean arterial blood pressure over baseline (Base) values (100%) after the insertion of a laryngeal mask airway (●) or tracheal tube (○). used than during subsequent measurements when the airway was secured with an ET or LMA (satisfactory condition noted in 46% during all baseline measurements vs 76% after the airway was secured; $P = 0.01$) (Table 2). The ophthalmologists considered the rapid and easy access to the eyes and the absence of movement of the surgical field to be major advantages of the LMA compared with conditions when a face mask was used. In the latter case, manipulations of the jaw and face mask required to maintain a patent airway interfered with IOP measurements.

Discussion

This study demonstrates that the use of the LMA provides better conditions for IOP measurements compared with a face mask and was not associated with IOP or hemodynamic changes. In contrast, tracheal intubation was associated with significant HR, systemic blood pressure, and intraocular pressure increases. This study also confirms our previous findings that the time-course of IOP changes after tracheal intubation are similar to the time-course of hemodynamic responses to tracheal intubation (2).

The mechanisms of IOP responses to tracheal intubation are uncertain. The acute changes in IOP are probably not simply responses to increases in arterial pressure. Although blood flow to the eye increases with tracheal intubation, the eye is capable of autoregulation of its blood supply (3,4). The increases in IOP associated with tracheal intubation may be secondary to increased sympathetic activity (4). Adrenergic stimulation may cause vasoconstriction and an increase in the central venous pressure, which has a closer relationship to IOP than systemic (arterial) pressure (4). In addition, adrenergic stimulation can produce an acute increase in IOP by increasing the resistance to the outflow of aqueous humor in the trabecular meshwork between the anterior chamber and Schlemm's canal (12).

Increased catecholamine and arterial blood pressure responses occur in adults who have undergone laryngoscopy without tracheal intubation (13). These data suggest that the major afferent source of the stimuli responsible for the adrenergic response may be the supraglottic, not the subglottic area. The supraglottic structures are distorted by the laryngoscope blade, whereas the subglottic area is stimulated after the tube passes through the vocal cords. Because inflation of the LMA cuff will cause some distortion of the pharynx and supraglottic structures, we would expect an acute adrenergic response to the insertion of the LMA in patients who are lightly anesthetized (9,14). Braude et al. (9) and Holden et al. (14) reported that hemodynamic and IOP responses, respectively, after the insertion of a LMA were attenuated compared with responses to tracheal intubation. However, we did not observe a significant hemodynamic or IOP response to the insertion of the LMA. Differences in the depth of anesthesia in our study and the previous studies may explain these differences (9,14). It is also possible that we missed the peak IOP response in some patients, because our measurements were made 15–30 s after placement of the airway device, and the peak response has been reported to occur at 20 s (14).

Holden et al. (14) recommended the use of the LMA for emergency intraocular surgery; however, in patients with penetrating eye injuries, the anesthesiologist must balance the risks of aspiration of gastric contents when the LMA is used against the risks of vitreous extrusion with increased IOP after tracheal intubation (2,4,10,14). The presence of the LMA in the hypopharynx may cause incompetence of the upper esophageal sphincter even with cricoid pressure (15). In addition, if the patient vomits, the lower portion of the laryngeal mask may prevent easy escape of the vomitus into the nose and oral passages, thereby directing it into the trachea (15,16). In acute eye injury cases, it may be safer to intubate the trachea after using pharmacologic agents (e.g., propofol, lidocaine, thiopental, opioid analgesics) to reduce IOP responses to tracheal intubation (4,17–20).

During our study, conditions were carefully controlled to ensure that factors other than insertion of the airway device were not responsible for changes in the IOP. For example, we used neuromuscular blocking agents to avoid increases in IOP associated with coughing or straining during insertion of the airway device. We also maintained a constant end-tidal concentration for ≥10 min to achieve comparable conditions between the two groups. Because the LMA is tolerated at a lighter depth of anesthesia than a tracheal tube (9), it may be possible to insert it without using neuromuscular blockade and perform IOP measurements even earlier than we reported in this study (6–8,10,21). In addition, insertion of the LMA is a technically simpler procedure than tracheal intubation (6–9,21) and is associated with a decreased risk for vocal cord trauma, which has been noted after even short periods of tracheal intubation (22).

Although the statistically significant differences in the time for insertion of a tracheal tube or LMA may not appear to be of clinical importance (39 vs 26 s), it may be possible to save 7–10 min of anesthesia time in children undergoing routine intraocular tension checks and examinations under anesthesia if the LMA is used rather than an endotracheal tube. Regardless of whether tracheal intubation is performed under deep halothane anesthesia or is facilitated by neuromuscular blockade, an additional 2–3 min is required to establish a satisfactory depth of anesthesia or adequate neuromuscular blockade, or both. In addition, the ophthalmologist will have to wait 3–4 min after tracheal intubation for the IOP to return to baseline values before a reliable measurement can be made (2). Extra time may also be required at the end of the procedure to antagonize residual neuromuscular blockade or eliminate halothane, or both, before the trachea can be extubated.

Although the differences in the oxygen saturation values between the two groups in our study were statistically significant, they were small, and no patient developed hypoxemia ($Spo_2 < 85\%$ for >15 s). However, a higher incidence of hypoxia was reported in a face mask group compared with a laryngeal mask group in children undergoing otological procedures (7). In that study and in our study, operative conditions were better with the use of the LMA compared with a face mask (7).

In conclusion, this study has shown that the insertion of an LMA during halothane-N_2O anesthesia in children is not associated with acute cardiovascular or intraocular pressure responses, whereas tracheal intubation is associated with increased HR, arterial blood pressure, and IOP. We would recommend the use of the LMA for routine IOP measurements in anesthetized children, because it provides better conditions for the measurements compared with a face mask and avoids the potential problems associated with tracheal intubation.

The authors thank the nurses and resident staff at Children's Hospital of St. Louis for their patience during the study and are grateful to Mia Bicknell for the secretarial assistance provided during the preparation of the manuscript. They are also grateful to Dr. A. I. J. Brain for the supply of the laryngeal mask airways.

Neuromuscular Pharmacology in Rat Neonates: Development of Responsiveness to Prototypic Blocking and Reversal Drugs

Michiko Okamoto, PhD, Jose L. Walewski, BS, Joseph F. Artusio, Jr., MD, and Walter F. Riker, Jr., MD

Departments of Pharmacology and Anesthesiology, Cornell University Medical College, New York, New York

The neonatal pharmacology of neuromuscular drugs was studied in vivo in newborn rats and in vitro in neonatal phrenic nerve-hemidiaphragm preparations. Drugs used to probe neuromuscular development in rat neonates were physostigmine, edrophonium, neostigmine, 4-aminopyridine, *d*-tubocurarine (dTc), and succinylcholine. The prejunctional actions of these drugs were monitored in relation to neonatal age by the appearance of stimulus-evoked repetitive discharge initiated by motor nerve endings and the occurrence and magnitude of the resulting enhancement of twitch tension. The occurrence and incidence of drug-induced fasciculations also served to track the development of functional motor nerve endings. Each of these prejunctional actions was inoperative until the third neonatal week, indicative of incomplete motor nerve development. In contrast, 4-aminopyridine, a nonanticholinesterase, evoked these prejunctional actions in 1-wk-old rat neonates. Neostigmine and edrophonium antagonized dTc as early as the first week; presumably, postsynaptic maturation had reached a functional level. 4-Aminopyridine also antagonized dTc at week 1. Rat neonates showed resistance to dTc blockade when tested by neonatal phrenic nerve-hemidiaphragm preparations in vitro. Relationships between age and 85%–95% transmission block declined to the adult level by week 5. This result indicates that in rat neonates, pharmacodynamic rather than pharmacokinetic mechanisms predominate in the development of responsiveness to dTc.

(Anesth Analg 1992;75:361–71)

The postnatal development of amphibian and mammalian neuromuscular junctions has been well defined (1–19). The structural and functional development of the rat neuromuscular junction achieves an adult level by the fifth postnatal week. The human neuromuscular junction exhibits an adult function and morphology by approximately the 12th postnatal week (3). This maturation process includes completion of myelination, disappearance of polyneuronal innervation, aggregation of postjunctional acetylcholine (ACh) receptors to form end plates, sensitivity to ACh, acetylcholinesterase (AChE) localization, and completion of functional and pharmacologic responsiveness (1,9–19).

Pharmacologically, however, classic neuromuscular drug effects have not been explored fully or quantitatively in either animal or human neonates. The present work reports and discusses the use of neonatal rat neuromuscular preparations in vivo and in vitro to study the pre- and postjunctional actions of *d*-tubocurarine (dTc), succinylcholine (SCh), neostigmine, edrophonium, physostigmine, and 4-aminopyridine (4-AP) on developing junctions. The principal aims were twofold: (a) to use well-defined pharmacologic probes in assessing developmental stages of mammalian neuromuscular junctions in vivo; and (b) to define the neonatal pharmacology of drugs having classical actions at neuromuscular junctions.

Methods

Rat pups aged 1–5 wk, born to Sprague-Dawley dams (Hill Top Farm, N.J.) were studied. All of the procedures used were in accord with AALAC guidelines. Dams in their last week of pregnancy were housed individually. Pup body weights were recorded at birth. These progressed from 10 to 50 g during the first three neonatal weeks. Pups were raised by their dams during the first three postnatal weeks. To ensure uniform nutritive conditions of the pups, the

number of pups per dam was limited to 10 at birth, 7 at postnatal week 2, and 4 at postnatal week 3. The pups started eating on their own by postnatal day 17 or 18. The findings obtained in the rat neonates were compared with those from adult control Sprague-Dawley male and female rats, weighing between 200 and 250 g (i.e., >7 wk of age).

Pups and adults were anesthetized with 25% urethane solution intraperitoneally, 6 μL/g body wt for a body weight <100 g and 5 μL/g body wt for a weight >100 g. The anesthetized animal was secured on a polystyrene board, and an unobstructed airway was ensured by tracheostomy. A carotid artery was catheterized for intraarterial (IA) drug injection. The carotid arteries were the only blood vessels accessible for cannulation in 1-wk-old rat neonates.

Isometric muscle contraction was obtained as follows. A leg was immobilized by fixation of the knee and foot to the polystyrene board. A gastrocnemius muscle and its innervation were exposed in situ. The corresponding sciatic nerve was cut centrally. The gastrocnemius tendon was detached from its insertion and connected to a force transducer (model FT-3, Grass Instruments Co., Quincy, Mass.). The output from the transducer was amplified and recorded (transducer amplifier model 13-4218 and recorder model 220, Gould, Cleveland, Ohio). The exposed tissue was protected with paraffin oil and the preparation temperature thermostatically held at 37°C by radiant heat.

Indirect muscle contractions were evoked by supramaximal single stimuli applied to the sciatic nerve through a bipolar platinum electrode from a stimulator (model S-88, Grass Instruments Co.) via an isolation unit. For direct muscle stimulation, needle electrodes were inserted into the gastrocnemius muscle heads, and neural transmission was blocked by dTc. Both indirect and direct stimuli consisted of 0.1-ms square-wave pulses delivered every 4 s. Tetanic stimuli of 5–400 Hz were delivered for 30 s.

To record muscle fasciculations, the output from the transducer was amplified 10 times that for recording normal twitch tension. Nerve stimulation was discontinued when recording muscle fasciculations. Fasciculations, when these occurred, were observed in exposed muscle and in the intact animal. Their incidence was recorded with regard to age at the physostigmine doses shown in Table 1.

To record motor nerve ending* activity, thoracic and lumbar laminectomies exposed the S-1 and L-6 ventral roots; these contain gastrocnemius motor axons. In these experiments, the sciatic nerve was left intact. The S-1 and L-6 roots were disconnected at their origin from the spinal cord and separated into small filaments. A reactive filament was placed on bipolar platinum recording electrodes leading to differential preamplifiers (model AM 502, Tektronix, Beaverton, Ore.) and displayed on a storage oscilloscope (model 4072, Gould). Thus, prejunctional actions of gastrocnemius motor nerve terminals were monitored antidromically, as detailed by other studies from this laboratory (20–23).

Table 1. Percent Incidence of Physostigmine-Induced Fasciculation in Neonatal and Adult Rats

Dose[a] (mg/kg SC)	Postnatal week Week 2	Week 3	Week 4	Week 5	Adult
0.5	0	0	50.0	100.0	100.0
1.0	0	0	72.7	100.0	100.0
2.0	0	12.5	75.0	100.0	100.0
5.0	0	27.2	100.0	—	—
10.0	0	40.0	100.0	—	—

SC, subcutaneous.
[a] $n > 5$ for each subcutaneous dose.

Compound action potentials of gastrocnemius muscle, elicited by motor nerve stimulation, were recorded by bipolar platinum microelectrodes. The output was amplified through a differential preamplifier (model AM 502, Tektronix) and displayed simultaneously with the nerve action potentials on the storage oscilloscope described.

The drugs administered IA were edrophonium chloride, neostigmine bromide, dTc chloride, and SCh chloride; physostigmine sulfate was administered subcutaneously (SC). Atropine sulfate (2 mg/kg IP) was used to prevent muscarinic effects. All drugs were purchased from Sigma Chemical Co. (St. Louis, Mo.), and the solutions were prepared in 0.9% NaCl. Concentrations of each drug, with the exception of dTc and SCh, were prepared to limit injection volumes to 25 μL/10 g body wt for weights <40 g and to 50 μL/100 g body wt for weights >40 g. The dTc was prepared in 200- or 400-μg/mL concentrations; SCh was prepared in 1- or 2-mg/mL concentrations. The dTc and SCh were infused through a carotid artery at 15–20 μL/min with a microinjection pump (model CMA/100, Bioanalytical Systems, Lafayette, Ind.), and dTc or SCh was infused until an 80%–95% neuromuscular block resulted. The dTc or SCh doses required for this were calculated from the total volumes injected. During the dTc or SCh experiments, respiration was maintained by a rodent ventilator (model 683, Harvard Apparatus and Instruments, South Natick, Mass.).

At the end of all experiments, the animals were killed with sodium pentobarbital (>50 mg/kg IP).

*Motor nerve endings include the distal Ranvier node, the myelinated axon leading to the unmyelinated nerve terminals, and the unmyelinated terminals.

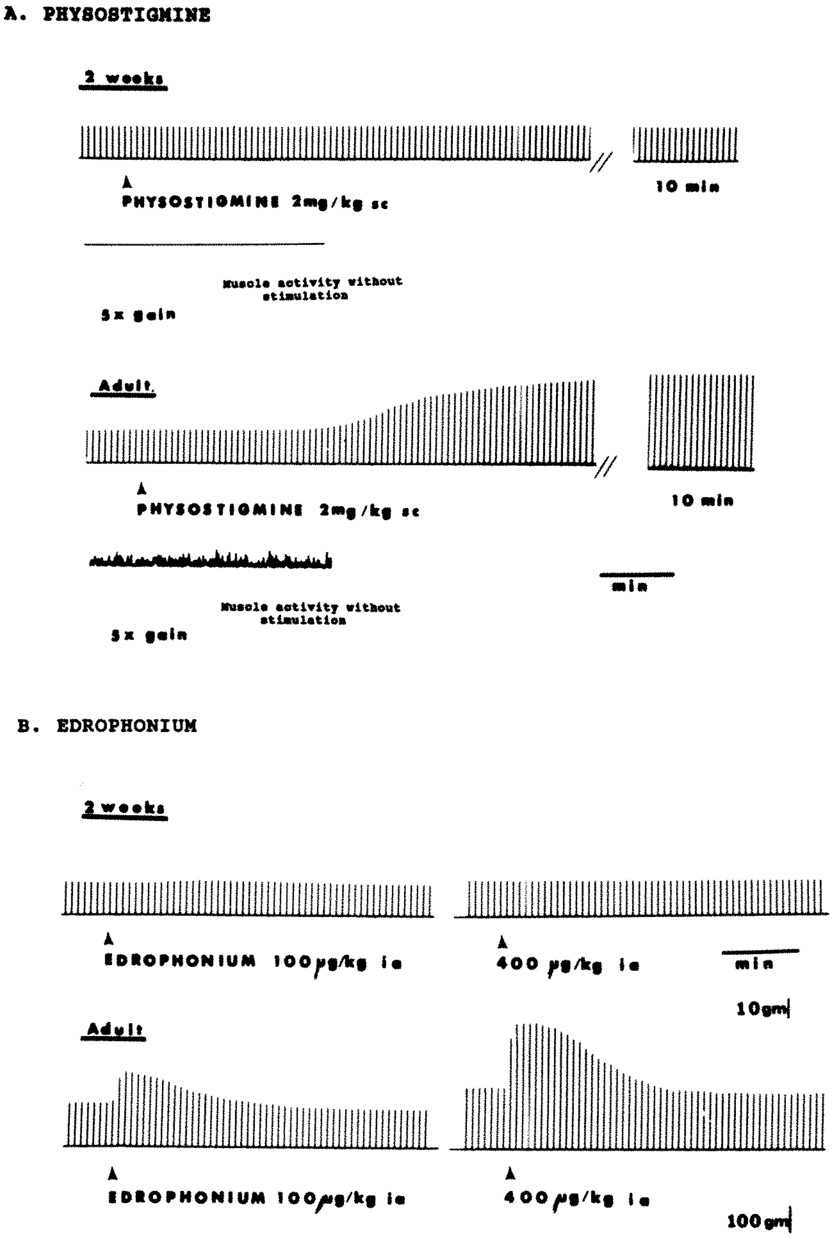

Figure 1. Physostigmine (**A**) and edrophonium (**B**) effects in a 2-wk-old rat neonate and an adult rat. Twitch potentiation and muscle fasciculation are absent in the rat neonate but are well-developed effects in the adult rat. In the drug-induced potentiations, the sciatic nerve was supramaximally stimulated at 0.25 Hz. Physostigmine and edrophonium injections are indicated by *arrows*. Muscle fasciculations were recorded in the absence of nerve stimulation and at a gain five times that used to record twitch tension. sc, subcutaneous; ia, intraarterial.

The neuromuscular blocking potency of dTc was studied in rat neonates of various ages, utilizing phrenic nerve-hemidiaphragm preparations in vitro. The muscle with its nerve was isolated and mounted in a Lucite chamber. The preparation was then bathed in Krebs' solution containing NaCl, 118 mM; KCl, 5 mM; $CaCl_2$, 2.5 mM; $NaHCO_3$, 30 mM; KH_2PO_4, 1 mM; $MgSO_4$, 1 mM; glucose, 11 mM. The pH was maintained at 7.4 when aerated with a mixture of 95% O_2 and 5% CO_2 (vol/vol%). The temperature of the bath was maintained at 36°C. The dTc concentrations studied were 1×10^{-6} and 1×10^{-5} M. The degree of neuromuscular block was calculated at the peak plateau effect of dTc; twitch tensions were measured before and after dTc and expressed as a percent block of twitch.

Statistical calculation for estimating group mean, standard error, and correlation coefficient was done by analysis of variance.

Results

Indirect Enhancement of Twitch Tension

Indirectly evoked twitch responses to the anticholinesterase drugs physostigmine and edrophonium are illustrated in Figure 1. The enhancement of

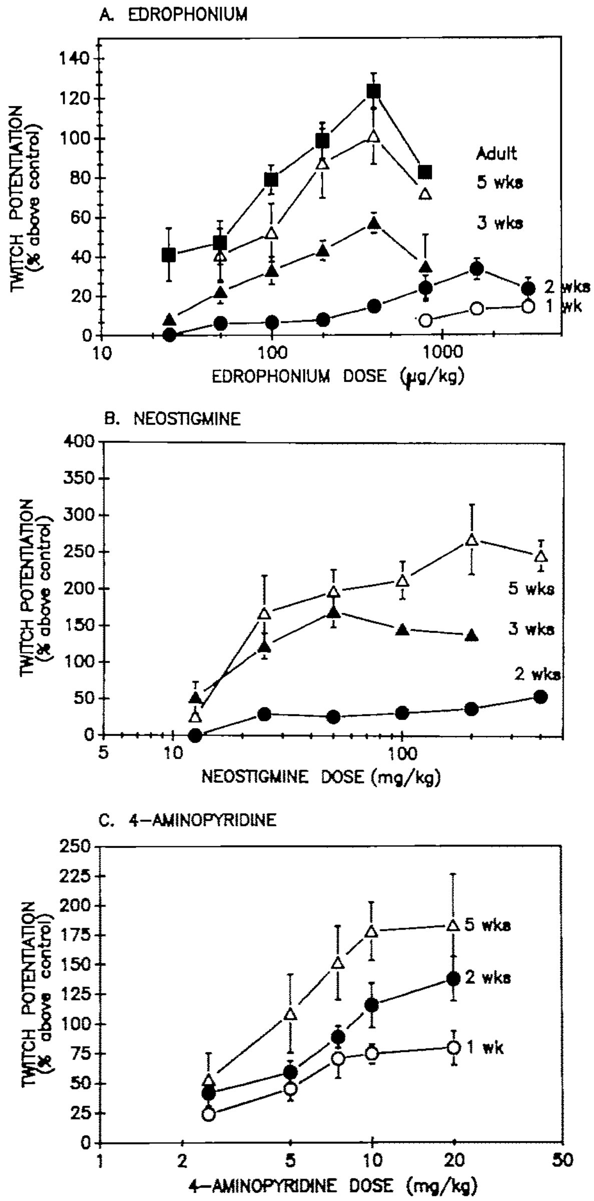

Figure 2. Dose- and age-related twitch potentiations plotted for intraarterial doses of edrophonium (A), neostigmine (B), and 4-aminopyridine (C). In all instances, sciatic nerve stimulation was supramaximal at 0.25 Hz. Maximal twitch potentiation (mean ± SE) is calculated as percent potentiation above control twitch. Each point represents the average of $n \geq 7$ experiments.

twitch tension (potentiation) caused by physostigmine, as seen in adult rats, was absent in 1- and 2-wk-old rat pups. Subcutaneous physostigmine doses as large as 10 mg/kg failed to produce potentiation in these rat neonates. By postnatal week 3, physostigmine potentiation appeared but was less than the response seen in the adult rat. The twitch potentiation evoked by edrophonium in the adult rats, like that of physostigmine, was absent in pups <3 wk old.

To determine whether the lack of potentiation in the 1–2-wk-old rat neonates is unique for these drugs, the nonanticholinesterase drug 4-AP was tested. Dose-twitch potentiation relationships, with respect to neonatal age, are plotted in Figure 2 for IA edrophonium, neostigmine, and 4-AP. These dose-range studies disclosed an insignificant twitch potentiation by neostigmine and edrophonium in the 2-wk-old rat pups compared with 3-wk-old pups and adults. The results of neostigmine were similar to those for physostigmine and edrophonium (Figures 1 and 2). At 3 wk and beyond, neostigmine and physostigmine twitch potentiations significantly exceeded those for edrophonium. In contrast to the threshold responses to physostigmine, edrophonium, and neostigmine with respect to enhancement of twitch tension in the 1- and 2-wk-old rat neonates, the threshold response of IA 4-AP was positive. The dose-response curves for edrophonium, neostigmine, and 4-AP in Figure 2 are seen to be dose and age dependent.

Actions on Neonatal Motor Nerve Endings

Neostigmine action on neonatal rat motor nerve terminals was investigated in 3-wk-old rat neonates given a 100-µg/kg dose IA. Figure 3 illustrates the repetitive action potentials recorded from ventral root fibers and a paired innervated muscle fiber after neostigmine dosing. As seen in Figure 3, repetitive motor nerve action potentials created a repetitive response in muscle. These events did not occur in 1- and 2-wk-old rat neonates.

In contrast to neostigmine, 4-AP in all 1- and 2-wk-old rat neonates tested caused both repetitive prejunctional firing (Figure 3) and significant twitch potentiation (Figure 2).

Drug-Induced Fasciculations

Rat neonates <2 wk old did not evidence physostigmine-induced fasciculations in doses as large as 10 mg/kg (Figure 1). In Table 1, the percent incidence of physostigmine fasciculations is tabulated with respect to dose and neonatal age. Rat neonates >3 wk old manifested a dose-related increase in the incidence of fasciculations. The adult rat response level was reached by week 5. Although not shown, the results with edrophonium and neostigmine did not differ.

Transmission Blocking Effects of Twitch-Potentiating Drugs

At large doses of edrophonium, transmission block occurred in rats ≥3 wk old (Figure 2). A threshold

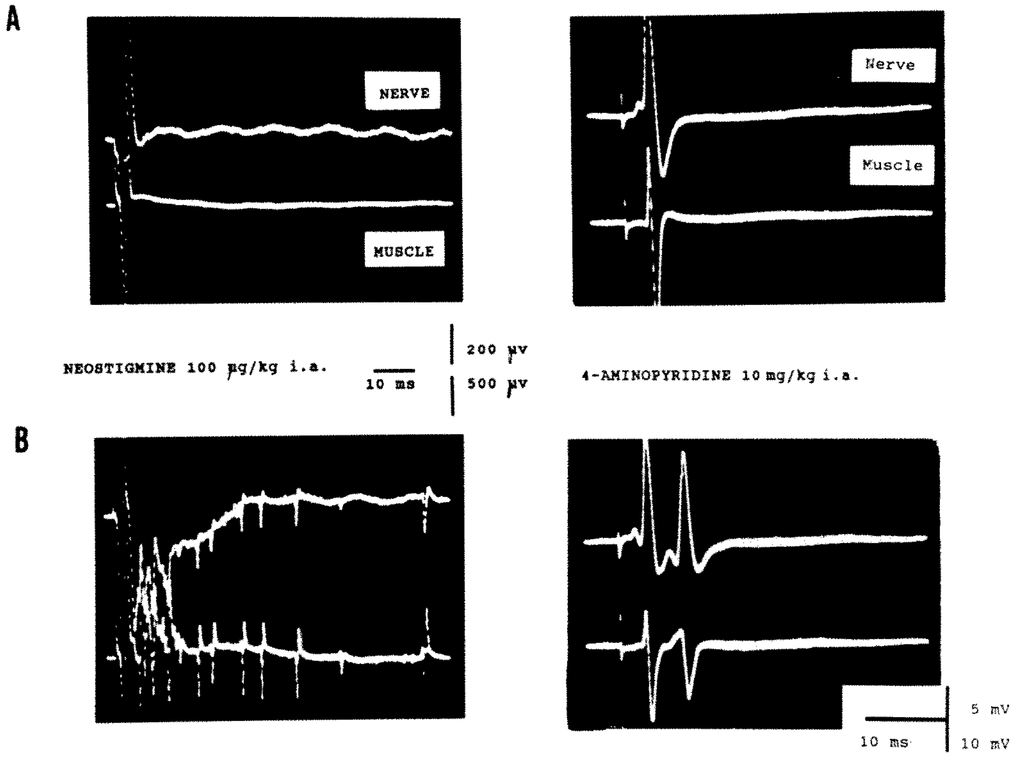

Figure 3. Neostigmine (*left*) and 4-aminopyridine (*right*) repetition induced in gastrocnemius motor nerve and muscle in a 3-wk-old rat neonate. Recordings were made from an innervating ventral root filament (S-1). *Top*: Nerve and muscle responses before drug administration. *Bottom*: Repetitive nerve and muscle action potentials recorded in response to single stimulation of the motor axon after intraarterial (i.a.) neostigmine (100 μg/kg) or 4-aminopyridine (10 mg/kg) injection. Correlation of the nerve and muscle events is evidenced by the fixed temporal relationship of their repetitive action potentials.

blocking action of neostigmine was visible in the 3-wk-old rat neonate; however, it could be increased at this point with larger neostigmine doses (not shown in Figure 2). A transmission blocking action did not occur with 4-AP.

Anticurare Action of Edrophonium and 4-Aminopyridine

To investigate the anti-dTc action of neostigmine, physostigmine, and edrophonium in the rat neonates, edrophonium was chosen as a prototype. Unlike the failure of edrophonium to potentiate twitch in 1- and 2-wk-old rat neonates, its anti-dTc action was demonstrable in the first neonatal week (Figure 4). The anti-dTc effectiveness of edrophonium increased with neonatal age and dose, as Figures 4 and 5A show. An adult response level was reached by week 5.

4-Aminopyridine antagonism of dTc was more effective than that of edrophonium (Figure 5B); 4-AP antagonized an 85%–95% dTc block completely in 1-wk-old rat neonates. The 4-AP anti-dTc efficacy was dose and age related (Figure 5B). Furthermore, 4-AP antagonism not only fully restored dTc-depressed twitch responses, but also potentiated twitch amplitude above the pre-dTc level. This occurred in relation to dose at all ages.

Responses to D*-Tubocurarine and Succinylcholine*

The dTc and SCh doses needed to produce an 80%–95% twitch block were calculated from the total volume of dTc or SCh infused and the body weight of the rat pup. Doses of dTc and SCh producing an equivalent level of neuromuscular block depended on neonatal age and body weight as a correlate of age. In pups <3 wk old, the average dose of either dTc or SCh needed to produce 80%–95% neuromuscular block was much larger than that for adult rats. The results are plotted in Figure 6. Figure 6A correlates the dTc doses necessary for 80%–95% block with the individual neonatal body weights as well as the average body weight for each age group. The correlation coefficients for the linear log-log plot of dTc dose versus body weights and ages was $r = -0.918$ ($P < 0.05$). Succinylcholine was studied in relation to rat neonatal body weight (Figure 6B), assuming neo-

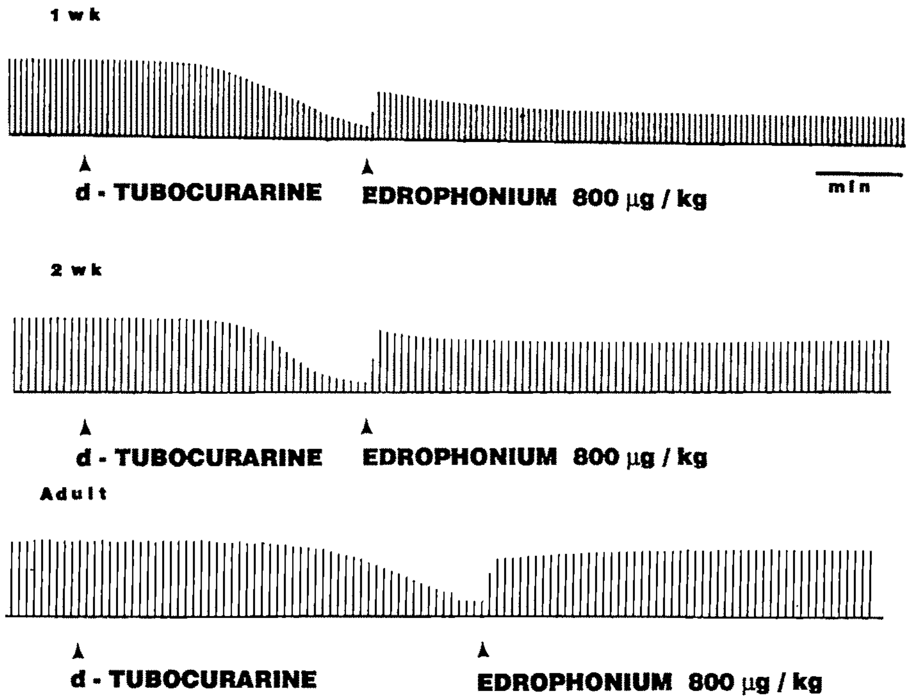

Figure 4. Anti-*d*-tubocurarine effect of edrophonium in rat neonates (1 and 2 wk) and in an adult rat. Twitch responses to single supramaximal stimulation of a sciatic nerve at 0.25 Hz. *d*-Tubocurarine was infused to produce 85%–95% neuromuscular block. Edrophonium (800 μg/kg) was injected intraarterially (*arrow*) when block reached its peak.

natal body weight to be a correlate of neonatal age. As Figure 6 indicates, the correlation coefficient in this case (Figure 6B) was $r = -0.916$ ($P < 0.05$). The dTc dose for 80%–95% block in adult rats was attained by the fifth neonatal week. The SCh dose for 80%–95% block in adult rats, like that for dTc, was reached in an estimated 5 wk.

Figure 7 shows the dose-age neuromuscular blocking effects of dTc on phrenic nerve-hemidiaphragm muscle preparations in vitro. As shown in Figure 7, the dTc blocking effect was age related. At 10^{-6} M, dTc did not cause neuromuscular block in 1- and 2-wk-old rat neonates; however, this concentration did produce an 89% block in 4-wk-old rat neonates. A 10-fold increase in dTc concentration (10^{-5} M) produced only a 25% block in 1-wk-old rat neonates but caused complete block in those >3 wk old. This approximated a 20-fold dTc sensitivity difference between 1- and 4-wk-old rat neonates.

Discussion

The failure of 1–2-wk-old rat neonates to generate neural repetitive firing and twitch potentiation after the administration of physostigmine, neostigmine, or edrophonium up to doses 65 times those that are effective for the adult rat points to an incomplete development of motor nerve endings at these ages. In classical studies, Standaert (20,21) showed conclusively that twitch potentiation of this type results from the generation of repetitive discharging by mammalian motor nerve endings and its transmission to muscle (see Figure 3). This sequence converts the muscle response to each single nerve stimulus to a tetanic form of contraction. This has since been confirmed in other studies (24–36).

Twitch potentiation is a simple but accurate measure of neural repetitive activity in that the whole muscle serves to integrate the total activity transmitted. Consequently, the absence of drug-induced twitch potentiation in the 1–3-wk-old rat neonate points to an incomplete development of motor nerve endings. This was confirmed by the experiments in which motor nerve endings were monitored for generation of repetitive activity; the lack of such activity paralleled the absence of twitch potentiation. Repetitive generation and twitch potentiation appeared by week 3, increasing progressively to an adult level by week 5.

The absence of repetitive firing and twitch potentiation in the 1–3-wk-old rat neonates points to an incomplete myelination. This accords with the morphologic findings of Webster (1) and Redfern (10). Because the triggering of repetitive activity in motor axons requires an interaction between their unmyelinated terminals and the corresponding distal Ranvier nodes (Figure 8), myelination between node and the origin of the unmyelinated terminals is necessary.

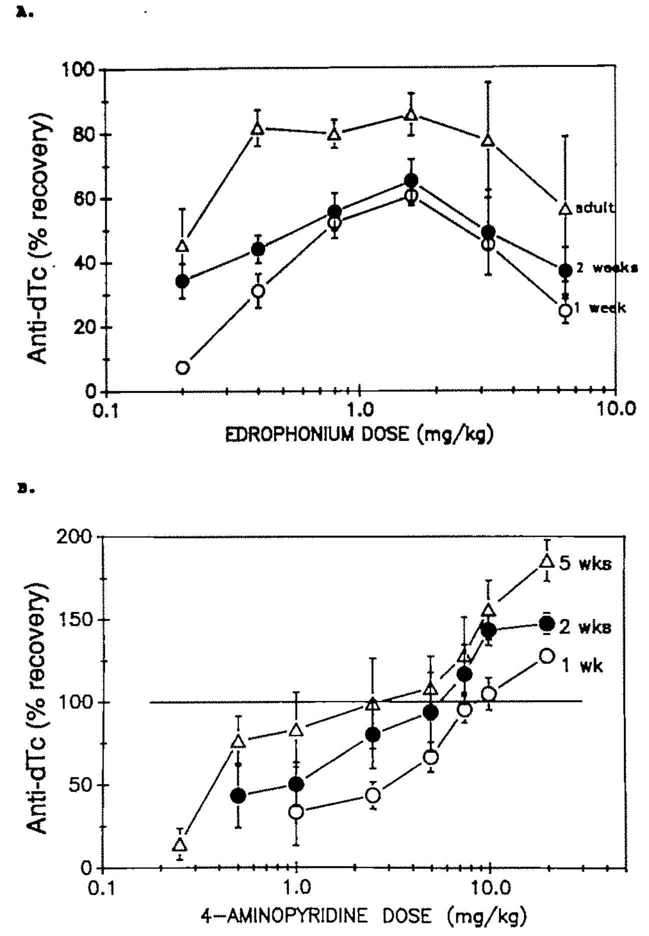

Figure 5. Dose-anti-dTc and age relationships are plotted for edrophonium (A) and 4-aminopyridine (B). The dTc was infused intraarterially to produce 85%–95% neuromuscular block before edrophonium or 4-aminopyridine administration. Peak recovery from dTc block (mean ± SE) calculated as percent recovery from maximal twitch depression. Each point represents the average of $n \geq 7$ experiments.

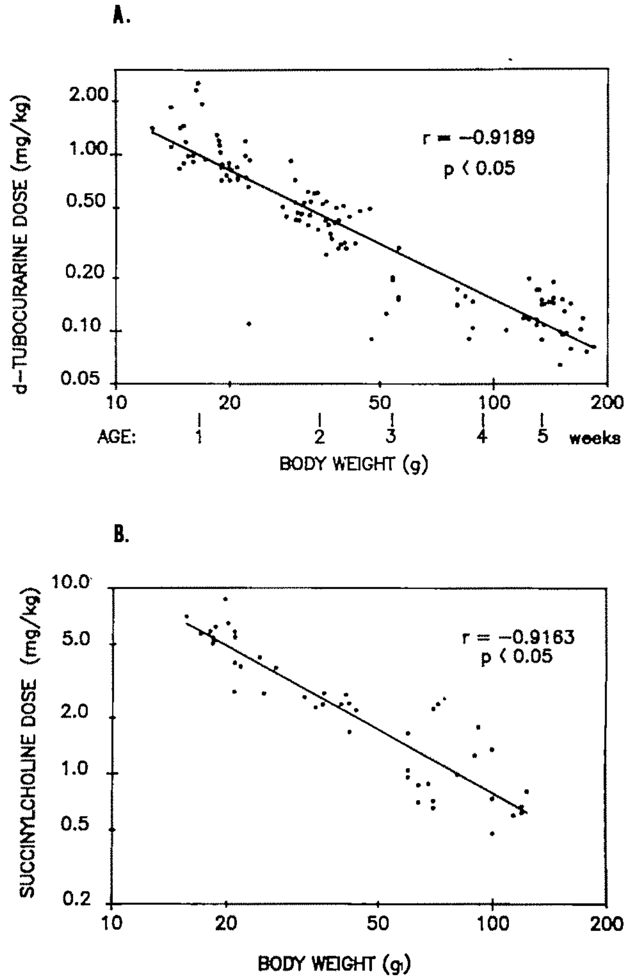

Figure 6. (A) Relationships between rat neonatal age and body weights and log *d*-tubocurarine doses (infused intraarterially) required to produce 85%–95% neuromuscular block. (B) Log succinylcholine doses (infused intraarterially) required to produce 85%–95% neuromuscular block in relation to rat neonatal body weights.

Neostigmine, edrophonium, or physostigmine alters the excitability properties of the unmyelinated terminals such that after their invasion by a single impulse, a prolonged depolarization follows (20,21,24–29,32,34,35,37–40). As Figure 8 depicts, the depolarized terminals serve as a long-lasting cathodal focus for reexcitation of the distal axonal nodes. Thus, a persisting motor nerve terminal depolarization must be at or above its distal node's threshold level for reexcitation (repetitive generation).

Further, an appropriate development of the unmyelinated nerve terminals per se must be attained if repetitive firing and twitch potentiation are to be evoked by physostigmine or related drugs. The need for intact unmyelinated nerve terminals is evidenced by the loss of a repetitive firing capacity after injury by certain neurotoxins that damage them (41–44). In this context, incomplete development of the motor nerve terminals per se in the 1–3-wk-old rat neonates probably contributes to their failure to generate repetitive firing and twitch potentiation.

In the 1–2-wk-old rat neonate, it may be that certain ion channels in their motor nerve terminals, requisite for the generation of repetitive firing, await development. Because calcium channel blockers, such as the metal ions Mg^{2+}, La^{3+}, Cd^{2+}, Co^{2+}, Ni^{2+}, or Mn^{2+}, antagonize the repetitive generating action of physostigmine and related drugs (45), it appears that these drugs act on at least one of the diverse calcium ion channels ubiquitous in excitable cells and nerve terminals (46–48). Brigant and Mallart (49) have demonstrated calcium channel(s) in the unmyelinated motor nerve terminals of the adult mouse.

A calcium channel activation required for repetitive firing may be that discussed by Tsien (47) and Tsien et al. (48). This channel, identified in central

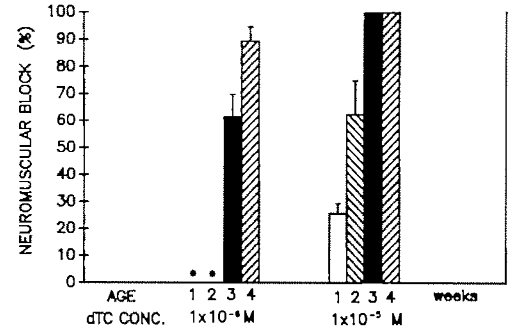

Figure 7. Effects of dTc on isolated phrenic nerve-hemidiaphragm muscle preparations in vitro in 1-, 2-, 3-, and 4-wk-old rat neonates. Mean dTc twitch block (±SE) calculated as a percent block of the control twitch before dTc. The two *bar groups* indicate the average blocking responses to 1 × 10^{-6} M dTc (*left*) and to 1 × 10^{-5} M dTc (*right*). *Asterisks* indicate zero block. *Solid and hatched bars* represent responses of 3- and 4-wk-old rat neonates at each of the two dTc concentrations tested. *Right-hand bars*: *open bar* shows response to 1 × 10^{-5} M dTc in 1-wk-old rat neonate; *hatched* (▨) *bar* shows response to 1 × 10^{-5} M dTc in 2-wk-old rat neonate. Each bar represents the average of $n \geq 5$ experiments.

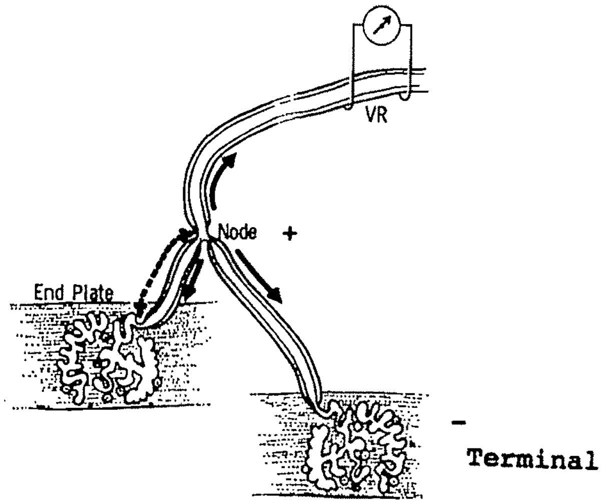

Figure 8. Mechanism of repetitive generation by motor nerve endings. Administration of an anticholinesterase drug, followed by single stimulation of the axon causes the unmyelinated terminals to develop a sustained depolarization (−); the unaltered distal axonal node returns quickly to its resting level, becoming electropositive (+) to the terminals. Current flow from positive source to negative sink (*dashed line*) reexcites the axon. Repetitive excitation recurs as long as the terminals remain sufficiently depolarized to enable current flow at a threshold for nodal excitation. Repetitive bursting is reinitiated with each single stimulus as long as the drug in the junction is at an effective level. Repetitive action potentials recorded from ventral root (VR) axons reflect this generating capacity of normal adult unmyelinated terminals (see Figure 3). (Adapted, with permission, from the *Annual Review of Pharmacology*, Volume 9, © 1969, by Annual Reviews, Inc.).

neurons and squid nerve terminals, is voltage dependent and inactivates slowly (half-life approximately 1 s). This behavior would provide a plateaued nerve terminal action potential appropriate for the generation of repetitive firing (cf. Figure 8). Conceivably, if such is the case, a putative calcium channel required for the generation of repetitive firing by physostigminelike drugs is undeveloped in the unmyelinated terminals of the 1–3-wk-old rat neonates.

Full manifestation of contractile potentiation in rat neonates at weeks 3–5 may be impaired by conduction block at branch points of unmyelinated intramuscular nerve fibers. At these points, the safety factor for conduction is reduced. This has been demonstrated in various unmyelinated nerve fibers and shown to be intensified by repetitive impulses (50,51). Although the earliest rat neonate is able to conduct and transmit single impulses, its well-known inability to maintain an indirect tetanus (3) probably contributes to conduction blocks in intramuscular nerves. Also contributory to decay of indirect tetanic maintenance are the neonatal polyneuronal innervation, incomplete myelination, and a minimal reserve in neonatal rat terminals. In view of these circumstances, failure of tetanic maintenance would be more pronounced in the first 2 wk of life.

Neostigmine and like drugs, as well as certain cholinergic agonists such as SCh (53), when administered to humans or intact animals in adequate doses, cause fasciculations that are generated by motor nerve endings, as first demonstrated for SCh by Standaert and Adams (53). This has since been confirmed (54,55). Fasciculations caused by ACh are similarly generated (28). Such drug-induced fasciculations are spontaneous discharges involving the same mechanism as that described for stimulus-dependent repetitive firings (Figure 8). Consequently, fasciculations are absent in the 1- and 2-wk-old rat neonate in which myelination is incomplete, but with the completion of myelination, fasciculations appear in 3-wk-old rat neonates and increase in intensity to an adult level by week 5. Thus, fasciculations, stimulus-dependent repetitive generation, twitch potentiation, and the completion of myelination concur in development in 3–5-wk-old rat neonates. These findings are commensurate with clinical reports describing little or no fasciculations in human neonates and infants after administration of SCh (7,56). Although SCh is not an anti-AChE, it has been shown to cause repetitive firing by adult motor nerve endings like that produced by physostigmine and related drugs (53,54).

4-Aminopyridine is a specific potassium channel blocker in both myelinated and unmyelinated axons and is not an anti-AChE (57). This drug differed sharply from the physostigminelike drugs in that 4-AP caused twitch potentiation, repetitive firing, and fasciculations in the 1–3-wk-old rat neonates. These effects in the youngest rat neonates appeared no different from those produced by the physostigmine-type drugs in the older rat neonates.

4-Aminopyridine when applied to axons including motor axons elicits repetitive firing (58,59). We propose that such 4-AP action on neonatal motor nerve axons, at both intra- and extramuscular sites, accounts for the twitch potentiation, repetitive firing, and fasciculation seen in the 1–5-wk-old rat neonates. This 4-AP action is attributable to blockade of neural potassium channels and thus to prolonged action potentials at these sites, leading to axonal repetitive firing (57).

In several species, 4-AP potentiates skeletal muscle contraction, in part due to block of muscle fiber potassium channels (57); however, in our studies, the failure of 4-AP to increase twitch tension responses in dTc-blocked muscle, directly stimulated, indicates that a 4-AP action on muscle probably does not account for the indirect twitch potentiation seen in the 1–5-wk-old rat neonates. In unpublished experiments, we have observed regularly that 4-AP produces neural repetitive discharge in the presence of 80%–90% dTc blockade. This happens in conjunction with dTc antagonism, continuing after a point of full recovery such that twitch potentiation follows. This is not seen with the neostigmine-type reversal drugs.

A number of studies (45,57,60) have demonstrated the anti-dTc action of 4-AP. Because of prolonged block of neural potassium channels by 4-AP, depolarization is maintained. During this period, calcium entry occurs. This event in the unmyelinated nerve terminals increases transmitter release (61,62), which in turn is considered to be the primary mechanism by which dTc and other nondepolarizing blockers are antagonized competitively. Because the neuromuscular transmitting system is functional in the 1-wk-old rat neonate, 4-AP was seen as an effective dTc antagonist.

The antagonism of dTc block in the 1-wk-old rat neonates by physostigmine and related drugs, as illustrated herein by edrophonium, is most simply explained by their anti-AChE action and transmitter accumulation in the primary cleft, leading to competitive antagonism of dTc. In this respect, the ultimate consequence of dTc antagonism by the anti-AChE drugs and 4-AP in the 1–5-wk-old rat neonates is the same.

Adult rats and humans differ only quantitatively in their pharmacodynamic responses to the drugs used in this study. The principal quantitative difference is the greater sensitivity of the adult rat to dTc and SCh compared with humans (63).

In both rat and human neonates, the requirement for SCh and dTc blockade is greater than in the adult (64–69). The rat neonate is exceptionally resistant to dTc block, as our studies demonstrate. This seems not to be the case in human neonates (70–72). Apart from this large quantitative difference, the pharmacodynamic responses of neonatal and adult rats are qualitatively like those in humans.

The discovery in rat neonates of a strong negative correlation for both dTc and SCh blocks (Figure 6) as functions of weight and age reveals another aspect of neonatal neuromuscular pharmacology. Resistance to SCh block in human infants was demonstrated by Stead (64) and has since been confirmed by others (56,64–68). It was considered that a larger volume of distribution in infants versus adults might explain an apparent resistance to SCh block (69,73); however, the need of some infants for SCh infusion rates three to four times that for others suggests that a pharmacodynamic component must be considered as well as a pharmacokinetic difference (56).

There is still no known explanation for the neonatal resistance to SCh. The increased requirement for SCh in blocking transmission in neonates may relate to polyneural innervation. These junctions are weakly functional and precede the formation of the single, mature junctions readily susceptible to the excitatory and blocking actions of SCh. Polyneuronal innervation may therefore be a principal factor in neonatal resistance to SCh actions.

Whether the dTc age-related resistance found in neonatal rats applies to human infants is uncertain (7,70,74). Matteo et al. (71) observed that the effective dTc dose for infants was threefold that required for an average child. They suggested that this may result from the retention of fetal ACh receptors.

For dTc, drug distribution volume may be thought to explain the larger doses required for block in rat neonates. Fisher et al. (72) found the steady-state distribution volume of this drug in humans in the following order: neonates > children > adults. Matteo et al. (71), however, found that resistance to dTc in infants cannot be explained entirely by distributional differences. In the present study, distributional differences do not offer a convincing explanation for the neonatal resistance to dTc. The 10-fold higher dose needed to produce a block in 1-wk-old rats (Figure 6) is 10 times greater than estimated neonatal distribution volumes. At most, the apparent volume of distribution in the youngest neonates is approximately five to six times that for the adult.

For the rat neonate, the studies of dTc block in a phrenic nerve-hemidiaphragm preparation in vitro apparently resolves this issue (Figure 7). The striking resistance of rat neonates to dTc and the gradual decrease of resistance with age were found in the in vitro neuromuscular system, just as these were seen in the in vivo preparations. In the in vitro preparations, distribution volume is not a factor. Thus, the strong resistance to dTc in rat neonates is chiefly pharmacodynamic and less likely pharmacokinetic. This points to an ongoing development of postjunctional receptor-ionophores during the first month of life in the rat neonate.

The large requirement of rat neonates (1–5 wk) for dTc and SCh block points to an incomplete development of postjunctional cholinoceptors. Presumably, the receptor binding affinity for these drugs is weak and readily dissociable. In this circumstance, the high concentrations of dTc and SCh necessary for block in the rat neonates may have also hindered edrophonium reversal.

The pharmacologic actions of the drugs used to probe the neuromuscular junctions of neonatal rats furnish further insight into the pharmacodynamic and temporal aspects of neuromuscular development.

The authors gratefully acknowledge Xiaoping Zhang, Michele Campione, and Dina Chenouda for their technical contributions in this work, and Dr. John J. Savarese, Professor and Chairman of Anesthesiology, New York Hospital-Cornell University Medical Center, for his critical review of this manuscript.

Epidural Test Dose and Intravascular Injection in Obstetrics: Sensitivity, Specificity, and Lowest Effective Dose

Pietro Colonna-Romano, MD, Nagaraj Lingaraju, MD, Steven D. Godfrey, MD,
and Leonard E. Braitman, PhD

Department of Anesthesiology, Hahnemann University Hospital, Philadelphia, Pennsylvania

The authors studied the sensitivity and specificity of several epidural test doses as markers of intravascular injection in laboring patients in a prospective double-blind, randomized study. Fifty-nine parturients were assigned randomly to receive an intravenous injection of either normal saline solution (3 mL, NS group) or 1.5% lidocaine with epinephrine 1:200,000 (1 mL, EPI-5 group; 2 mL, EPI-10 group; or 3 mL, EPI-15 group). The EPI-5 and EPI-10 doses were diluted to 3 mL volume with normal saline solution. All injections were given during uterine diastole. Maternal heart rate was monitored with a pulse oximeter. An observer who was unaware of the study treatment recorded the baseline and the peak maternal heart rate within the first minute after the injection and questioned the patient about tinnitus, dizziness, metallic taste, and palpitations. He then recorded his opinion as to whether the patient had received the saline or the test solution. Analysis of the maternal heart rate showed an average increase (baseline-to-peak criterion) of 8 ± 10 beats/min (mean ± SD) in the NS group. In the other groups, the increase was 21 ± 8 (EPI-5 group), 31.5 ± 13 (EPI-10 group), and 29 ± 9 beats/min (EPI-15 group). A baseline-to-peak criterion of >10 beats/min identified all intravascular injections in the EPI-15 (by design) and EPI-10 groups (15 of 15 and 14 of 14, respectively) with a sensitivity of 100%. Specificity was 73% (11 of 15 true negatives). The calculated areas under the receiving operating characteristic curves for the EPI-5, EPI-10, and EPI-15 groups were, respectively, 0.83 ± 0.8 (SE), 0.91 ± 0.5, and 0.93 ± 0.5. For the EPI-10 and EPI-15 groups, positive predictive value (+PV) ranged from 24% to 41% (assuming a prevalence between 8% and 16%). The negative predictive value (−PV) was 100%. The observer also correctly guessed the treatment of all patients in the EPI-10 and EPI-15 groups. Thus, the sensitivity was 100%, whereas the specificity reached 93% (14 of 15 true negatives). For the observer, the positive predictive value was 55%–73% and the negative predictive value 100%. Analysis of the symptoms (alone and in combination) exhibited low sensitivity (<67%). We conclude that (a) a test dose containing either 10 or 15 μg of epinephrine is 100% sensitive as a marker of intravascular injection (area under the receiving operating characteristic curves 0.91–0.93 and negative predictive value 100%); (b) the positive predictive value of this technique may range between 55% and 73%; and (c) 27%–45% of epidural catheters may be unnecessarily removed in the presence of a positive test.

(Anesth Analg 1992;75:372–6)

The use of 15 μg of epinephrine in the epidural test dose (ETD) as a marker of intravascular injection was first described by Moore and Batra (1). Their study showed an increase in mean heart rate of approximately 30 beats/min in healthy nonpregnant volunteers after an intravenous injection of 15 μg of epinephrine. Since then, the use of epinephrine as a component of an ETD has been widespread.

In 1990, Guinard et al. (2) determined the sensitivity of an epinephrine-containing ETD, as well as its lowest effective dose in healthy nonpregnant volunteers. They concluded that 10 μg of epinephrine is the lowest effective dose and that the agent is 100% sensitive in detecting intravascular injection; however, the efficacy of an epinephrine-containing ETD used to detect intravascular injection in laboring patients has been questioned because of the wide variability in maternal heart rate (MHR) (3).

We designed this study to assess the sensitivity and specificity of an epinephrine-containing ETD in laboring patients, as well as its lowest effective dose in detecting an unintentional intravascular injection.

was obtained from each subject. Fifty-nine laboring, unmedicated women (cervical dilatation >4 cm, uterine contractions at $\leq$3–4-min intervals) were enrolled in the study after they requested lumbar epidural analgesia. Their ASA physical status was I or II after an uncomplicated pregnancy. Patients with a history of hypertension of any etiology were excluded. The MHR was continuously monitored with a pulse oximeter (Nellcor, Hayward, Calif., model N-100, with a filtering time constant of approximately 7 s). A noninvasive blood pressure cuff was used to measure arterial blood pressure every 3 min. Fetal heart rate (FHR) was displayed continuously. Uterine activity was monitored with an external tocodynamometer or an internal uterine pressure catheter. Each patient received an intravenous infusion of 700–1000 mL of crystalloid solution through a peripheral catheter inserted into a vein in the dorsum of the hand. A lumbar epidural catheter was then inserted and taped in place.

An observer (either an attending anesthesiologist or a resident with >6 mo in the anesthesiology program) who was unaware of the study treatment established a baseline MHR. This was defined as a stable rate with no variability for four to five consecutive beats in the absence of uterine contractions.

The patients were then sequentially assigned to one of the following four groups: NS, EPI-5, EPI-10, or EPI-15. Fifteen patients received 3 mL of normal saline solution intravenously (NS group); other subjects were given an intravenous injection of 1.5% lidocaine with epinephrine 1:200,000. Specifically, 15 patients in the EPI-5 group received 1 mL; 14 patients in the EPI-10 group received 2 mL; and 15 patients in the EPI-15 group received 3 mL of the test solution. The EPI-5 and EPI-10 test doses were diluted to 3 mL with normal saline solution. All injections were given in the absence of uterine contractions and *immediately* after the establishment of baseline MHR. Parturients who developed uterine contraction within 1 min after the intravenous injection were also included in the study. An observer who was unaware of the study treatment then recorded the peak MHR, which was defined as the most rapid heart rate noted on the pulse oximeter within 1 min after the intravenous injection. The observer also questioned patients about the presence of tinnitus, dizziness, metallic taste, and palpitations and recorded their answers as well as his own opinion as to whether patients had received the test or the saline solution. No specific guidelines were given to the observer to discriminate among the groups, and the observer was not aware that different test doses were used. An obstetric nurse (blinded) and the authors (not blinded) observed the FHR tracing for signs of fetal distress.

We used the Newman-Keuls test to compare the four peak MHRs and estimated the lower bound of the 95% confidence interval from the EPI-15 group (peak MHR) to discriminate among the groups. We then calculated the sensitivity and specificity of the increase in MHR (baseline-to-peak criterion) in the four groups. The areas under the receiving operating characteristic (ROC) curves for each study group assessed overall performance of this test (range 0.5–1.0). A ROC curve plots 1 − specificity on the horizontal axis against the sensitivity on the vertical axis at various possible cutoff points. Thus, in effect, a ROC curve displays the trade-offs between sensitivity and specificity that a diagnostic test allows. The ROC curves and the area under the ROC curves were determined with LABROC 1, a program for IBM-PC-compatible microcomputers based on maximal likelihood estimation of a binormal ROC curve. LABROC 1 uses a set of continuously distributed data. The positive predictive value (+PV) determined the diagnostic accuracy in the presence of a positive test (increase in MHR). The negative predictive value (−PV) determined the diagnostic accuracy in the presence of a negative test (no increase in MHR). Sensitivity and specificity of the observer's clinical evaluation were also calculated, along with +PV and −PV. Finally, evaluation of the four symptoms as markers of intravascular injection of ETD was assessed by calculating specificity and sensitivity.

Table 1. Peak Maternal Heart Rate Increases in the Four Study Groups

Study group	Peak MHR (beats/min above baseline)	SD
NS (n = 15)	8	±10
EPI-5 (n = 15)	21	±8
EPI-10 (n = 14)	31.5	±13
EPI-15 (n = 15)	29	±9

MHR, maternal heart rate; NS, normal saline solution (3 mL IV); EPI-5 (1 mL IV), EPI-10 (2 mL IV), EPI-15 (3 mL IV), 1.5% lidocaine with epinephrine 1:200,000.

Data are means ± SD; Newman-Keuls test: NS < EPI-5 < EPI-10 = EPI-15 ($P < 0.05$).

Results

The results of the analysis of the peak MHR are shown in Table 1. The Newman-Keuls comparison test of the four peak MHRs showed NS < EPI-5 < EPI-10 = EPI-15 ($P < 0.05$). In the EPI-15 group, the average increase of the peak MHR was 29 ± 9 beats/min (mean ± SD) above the baseline. Using the lower bound of the 95% confidence interval for the EPI-15 group, we accepted an increase >10 beats/min above the baseline as diagnostic of intravascular injection of ETD. We then calculated sensitivity and specificity of the peak MHR in the four groups.

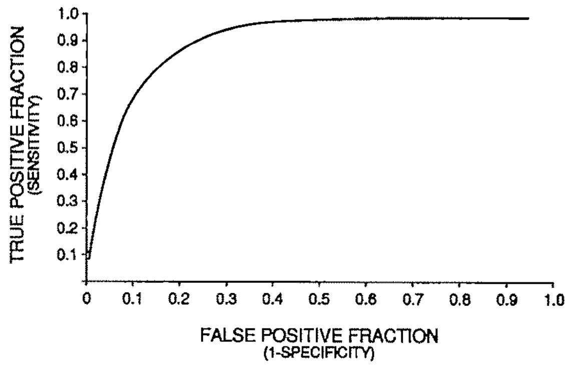

Figure 1. ROC curve and area under the curve assessing the level of diagnostic accuracy in distinguishing 15 patients in the NS group from 14 patients in the EPI-10 group. Area = 0.9289; SEM = 0.0554.

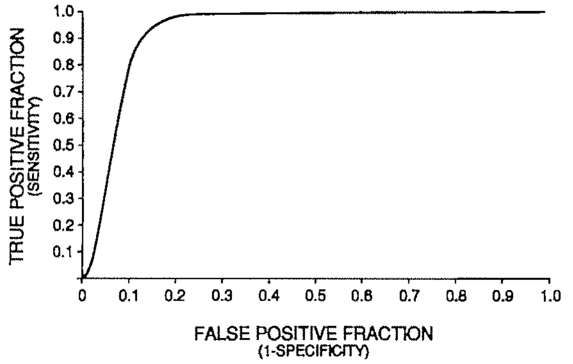

Figure 2. ROC curve and area under the curve assessing the level of diagnostic accuracy in distinguishing 15 patients in the NS group from 15 patients in the EPI-15 group. Area = 0.9107; SEM = 0.0539.

Table 2. Sensitivity and Specificity of the Peak Maternal Heart Rate and of the Observer Evaluation in the Four Study Groups

Study group	Peak MHR	Observer evaluation
Sensitivity		
EPI-5	87% (13/15 TP)	67% (10/15 TP)
EPI-10	100% (14/14 TP)	100% (14/14 TP)
EPI-15	100% (15/15 TP)	100% (15/15 TP)
Specificity		
NS	73% (11/15 TN)	93% (14/15 TN)

MHR, maternal heart rate; NS, normal saline solution (3 mL IV, *n* = 15); EPI-5 (1 mL IV, *n* = 15), EPI-10 (2 mL IV, *n* = 14), EPI-15 (3 mL IV, *n* = 15), 1.5% lidocaine with epinephrine 1:200,000; Sensitivity, number of true positives divided by the number of true positives plus false-negatives; Specificity, number of true negatives divided by the number of true negatives plus false-positives; TP, true positive; TN, true negative.

Table 3. Sensitivity and Specificity of the Four Symptoms Attributable to the Systemic Effects of the Test Dose

	Symptom			
Study group	Metallic taste	Dizziness	Palpitations	Tinnitus
Sensitivity				
EPI-5	1/15	4/15	4/15	0/15
EPI-10	3/14	6/14	3/14	0/14
EPI-15[a]	2/15	5/15	7/15	4/15
Specificity				
NS	13/15	13/15	14/15	15/15

NS, normal saline solution (3 mL IV, *n* = 15); EPI-5 (1 mL IV, *n* = 15), EPI-10 (2 mL IV, *n* = 14), EPI-15 (3 mL IV, *n* = 15), 1.5% lidocaine with epinephrine 1:200,000.

Sensitivity, number of true positives divided by the number of true positives plus false-negatives; Specificity, number of true negatives divided by the number of true negatives plus false-positives.

Sensitivity of the symptoms analyzed in combination reached 67% in the EPI-15 group.

The baseline-to-peak criterion identified all the intravascular injections in the EPI-15 group by design (the lower bound of the 95% confidence interval was calculated from the EPI-15 group) and in the EPI-10 group with a sensitivity of 100% and a −PV of 100%. Specificity of this test was 73% (11 of 15 true negatives), and the +PV ranged between 24% and 41%, assuming a prevalence of unintentional intravenous cannulation between 8% and 16%. The areas under the ROC curves for the EPI-10 and EPI-15 groups are displayed, respectively, in Figures 1 and 2. They were 0.83 for the EPI-5 group, 0.91 for the EPI-10 group, and 0.93 for the EPI-15 group.

The observers were also able to identify all the intravascular injections of ETD in the EPI-15 and EPI-10 groups with a sensitivity of 100%. Based on clinical evaluation, specificity reached 93% (14 of 15 true negatives). Results are shown in Table 2. The +PV was 55%–73% (prevalence 8%–16%), and the −PV 100%.

Sensitivity and specificity of the four symptoms, attributable to the systemic effects of an intravascular injection of ETD, were also calculated and did not reach clinical significance. The results are shown in Table 3.

The FHR monitor did not show any tracings indicative of fetal distress, and no medical intervention of any kind was ever required during the performance of the study. Noninvasive arterial blood pressure measurements provided frequently spurious results (movement artifacts), and the data were not used in the study.

Discussion

The intravenous injection of toxic doses of local anesthetics may cause seizures, cardiac arrest, and death (4). To prevent this occurrence during the performance of an epidural block, the concept of an "epidural test dose" (ETD) was developed.

An ETD should reliably provide an indication of unintentional intravenous insertion of an epidural catheter. The frequency of this mishap has been reported to be in the range of 3%–5% in the general population (5) and between 8% and 16% in pregnant patients (6), probably due to dilated epidural vessels (7).

Several techniques and agents have been proposed for use as ETDs. Since Moore and Batra (1) demonstrated a predictable heart rate increase after an intravenous injection of epinephrine (15 μg) in nonpregnant volunteers, the use of this agent as a marker for intravascular injection has become common. Recently, it was shown that the same heart rate changes could be induced with intravenous epinephrine (10 but not 5 μg) in nonpregnant volunteers (2).

In laboring patients, the sensitivity and specificity of epinephrine as a marker for intravascular injection are low (3) because of the wide variability in MHR. Isoproterenol has been suggested to replace epinephrine (8) as a component of an ETD in obstetrics; however, healthy and preeclamptic parturients have different chronotropic responses to the drug (9). The sensitivity of ephedrine is poor (<72%) (10). Finally, microbubbles of air have been found to be a reliable marker; however, the technique requires the use of a Doppler monitor over the precordium, and its placement must be "adequately confirmed and rechecked after changes in patient position" (11).

Our study shows that epinephrine is a sensitive marker of intravascular injection in laboring patients. Although analysis of the ROC curves (0.91–0.93) indicates acceptable overall performance of this test, a −PV of 100% provides strong evidence of its safety (absence of false-negative results). This conclusion is supported by the sensitivity of the baseline-to-peak criterion within 1 min and confirmed by the ability of the observer, who was unaware of the study treatment, to recognize all of the intravenous injections of either 10 or 15 μg of epinephrine.

The 1-min observation time was chosen because maximal changes in heart rate due to the injection of intravenous epinephrine occur within 30–45 s (1). Even though the venous return time from the epidural veins to the heart has never been compared with the venous return from the hand, 1 min closely approaches one circulation time in many parturients. In addition, limiting the MHR observation time to 1 min after the intravenous injection reduces the possible number of pain-induced MHR variations due to uterine contractions, and this in turn may improve the sensitivity and specificity of this technique. The importance of limiting the observation time to 1 min is also supported by the findings of Leighton et al. (3) who administered epinephrine (15 μg IV) to laboring parturients and noted a statistically significant increase in MHR at 45 s after the injection but not at 60 or 90 s. Indeed, other studies (12) in which MHR variations were observed for longer periods of time do not support the use of MHR accelerations as an indicator of intravascular injection in laboring parturients. Cartwright et al. (13) reduced the MHR observation time to 1 min after the epidural injection of ETD and showed that 24% of laboring parturients still had an MHR acceleration within that 1 min; however, in their study the criteria for defining the baseline MHR were not specified, and the time chosen to establish a baseline MHR ("during a period of uterine quiescence while the woman was lying comfortably") did not correlate temporally with the actual placement of the epidural catheter. A higher baseline MHR may be expected under those circumstances. In our study, to test our technique under clinical conditions we decided not to exclude those parturients who did experience uterine contractions within 1 min after the intravenous injection of ETD.

The components of an ETD should be safe for the baby as well as for the mother. Intravenous epinephrine causes a dose-dependent temporary reduction in uterine blood flow in animals (14) and may compromise fetal well-being in humans. In gravid ewes, 10 μg of intravenous epinephrine reduces uterine blood flow by 30%, and 20 μg causes an almost 50% decrease with no changes in FHR pattern (14). These reductions in uterine blood flow compare favorably with the 100% decrease noted in humans when intrauterine pressures reach 30–40 mm Hg (normal uterine contraction) (15). By monitoring the FHR we did not detect any signs of fetal distress in our patients after the injection of intravenous epinephrine, and this is in agreement with animal (14) and human studies (16). The safety of epinephrine in patients with a compromised uteroplacental reserve, as in preeclampsia, has yet to be determined.

Epidural test doses may also unintentionally be administered intrathecally; therefore drugs used as ETDs must be safe when injected into this compartment. Lidocaine (100 mg) (17) and chloroprocaine (100 mg) (18) are sensitive markers of intravenous injection and induce unmistakable symptoms in healthy male volunteers. However, if injected intrathecally in parturients, lidocaine may result in an undesirably high level of subarachnoid block and chloroprocaine carries the potential risk (19) of neurotoxicity. A smaller dose of lidocaine (45 mg) is not an accurate marker of intravascular injection in laboring patients (20). The safety of intrathecal isoproterenol has not been determined.

Specificity is also an essential feature of an ETD. A low incidence of false-positive results will avoid the unnecessary repetition of the procedure (replacement of a correctly inserted epidural catheter). In this study, the baseline-to-peak criterion reached 73%

specificity (11 of 15 true negatives) with a +PV of 24%–41%, whereas the observer's evaluation was 93% specific (14 of 15 true negatives) with a +PV of 55%–73%, suggesting that a blinded observer can clinically differentiate between the pattern of epinephrine-induced MHR accelerations (true-positive) and the pattern of pain-induced MHR accelerations (false-positive). This is not surprising and is in agreement with the previously mentioned study of Leighton et al. (3) in which the blinded investigator correctly distinguished between patients given epinephrine and those receiving normal saline solution despite the low sensitivity (50%) and specificity (20%) of their baseline-to-peak criterion. The different patterns of MHR accelerations in laboring parturients (epinephrine induced vs pain induced) were graphically recorded by van Zundert et al. (16) with the use of a direct electrocardiographic mode of FHR monitor located over the mother's precordium. The pattern of epinephrine-induced tachycardia was also described by Moore and Batra (1) in their original study in male volunteers as a rapidly developing, short-lived increase in heart rate (approximately 30 beats/min above the baseline) that followed intravenous injection (20–40-s delay) and returned to preinjection values within 25–35 s. Our observer was always able to recognize epinephrine-induced tachycardia in the EPI-15 and EPI-10 groups. He was also able to identify tachycardia from other sources (>10 beats/min above the baseline) in the NS group 75% of the time (4 of 15 false-positive by the baseline-to-peak criterion vs 1 of 15 false-positive based on the observer's evaluation). In practical terms, a +PV of 55%–73% implies that a positive test may yield false-positive results 45%–27% of the time, leading to unnecessary replacement of the epidural catheter.

Finally, in our study 10 μg of epinephrine was as effective as 15 μg in detecting intravascular injection. The epinephrine-induced reduction in uterine blood flow in animals has been shown to be dose dependent (14); therefore the use of 10 μg in humans may be warranted.

In conclusion, in this study we found that (a) epinephrine is a sensitive marker of intravascular injection in laboring patients; (b) within 1 min after injection, the baseline-to-peak criterion was a reliable indicator of intravenous injection; (c) 10 μg of epinephrine is as effective as 15 μg; (d) symptoms attributable to the systemic effects of our ETD were neither sensitive nor specific; (e) the pattern of epinephrine-induced tachycardia could be clinically differentiated from tachycardia from other sources; and (f) on the basis of our observer's evaluation, between 27% and 45% of epidural catheters may be unnecessarily repositioned in the presence of a positive test.

We thank J. C. Horrow, MD, for his valuable suggestions concerning the preparation of this manuscript.

Headache After Spinal Anesthesia for Cesarean Section: A Comparison of the 27-Gauge Quincke and 24-Gauge Sprotte Needles

David C. Mayer, MD, Daniel Quance, MD, FRCPC, and Sally K. Weeks, MBBS, FFARCS

Department of Anaesthesia, McGill University, and Royal Victoria Hospital and Jewish General Hospital, Montreal, Quebec, Canada

A high incidence of postdural puncture headache (PDPH) occurs after spinal anesthesia for cesarean section. To examine this problem, a study was conducted with the recently developed 24-gauge Sprotte and 27-gauge Quincke needles in patients undergoing elective and emergency cesarean section (n = 298). The needle to be used was assigned in a random manner: group I, 27-gauge Quincke (n = 147); group II, 24-gauge Sprotte (n = 151). During the postoperative period, patients were visited daily and asked specifically about the presence and severity of headache. The overall incidence of PDPH was 2% (n = 6), five in the Quincke group (3.5%) and one in the Sprotte group (0.7%). There was no significant difference in the incidence of PDPH between the two groups. Five headaches were classified as mild, and only one was moderate to severe. All headaches resolved quickly with conservative management and without blood patch. The authors conclude that the choice between a 27-gauge Quincke and a 24-gauge Sprotte needle does not influence the incidence of PDPH after spinal anesthesia for cesarean section.

(Anesth Analg 1992;75:377–80)

Spinal anesthesia for cesarean section is a popular and effective technique. Advantages over epidural block include the absence of risk of systemic local anesthetic toxicity, simplicity of technique, and rapid onset of surgical anesthesia; however, there is an inevitable risk of postdural puncture headache (PDPH) after spinal anesthesia, and until recently, the incidence of this complication was high enough to limit its use for cesarean section. The introduction of smaller gauge needles and of different needle-tip designs has created renewed enthusiasm for this technique. The 24-gauge Sprotte needle is associated with a very low incidence of spinal headache (1), and the widely used Quincke needle is now available in 26-, 27-, 29-, and 30-gauge sizes. The goal of this study was to compare, in a randomized clinical trial, the incidence of PDPH in patients undergoing cesarean section who received spinal anesthesia with either a 24-gauge Sprotte or 27-gauge Quincke needle.

Methods

The study was approved by the Institutional Ethics Committees of both participating hospitals (Royal Victoria Hospital and Jewish General Hospital). Two hundred ninety-eight patients consenting to spinal anesthesia for elective and emergency cesarean section were studied and were warned about the possible development of PDPH. Age, height, weight, gravidity, and parity were recorded for each patient. Group I (n = 147) had spinal anesthesia administered with a 27-gauge Quincke needle (Becton-Dickinson, Rutherford, N.J.); in group II (n = 151), the 24-gauge Sprotte needle was used (Pajunk, Geisingen, Germany). Patients received 1–1.5 L of intravenous normal saline solution at room temperature before block unless surgery was extremely urgent. The spinal needle was inserted at the L2-3 or L3-4 interspace in the sitting or lateral decubitus position, depending on the anesthetist's preference. Blocks were performed by staff, fellows, and residents under supervision. The bevel of the Quincke needle was kept parallel to the long axis of the dural fibers. An introducer was used in all patients. Hyperbaric 0.75% bupivacaine with 8.25% dextrose was the sole local anesthetic agent in the first 100 patients and the anesthetist chose a dose with the aim of obtaining a T-4 sensory

0003-2999/92/$5.00

block (dose range 10.5–15 mg). Preservative-free morphine (0.2 mg) was added to the syringe containing bupivacaine in all subsequent patients. At the Royal Victoria Hospital only, a transdermal scopolamine patch (1.5 mg) was placed at the time of surgery for emesis prophylaxis. The following information was recorded for each patient: number of attempts at puncture, position during block, bupivacaine dose, cephalad level of anesthesia obtained, occurrence of paresthesias, total amount of intravenous fluid administered, intraoperative analgesic supplement requirement, and the amount of ephedrine administered. Patients were seen daily by an anesthetist at the Royal Victoria Hospital and by a trained nurse at the Jewish General Hospital until discharge and were directly questioned at each visit about the presence of back pain and headache. A headache that was worse when sitting and relieved in the supine position was considered to be a PDPH and was classified according to severity: class I, mild headache when sitting or ambulating; class II, moderate to severe headache when sitting or ambulating; class III, moderate to severe headache when supine.

On each day that a PDPH was reported, patients were asked to score it on a standard 100-mm visual analogue scale. They were initially offered conservative management consisting of horizontal bed rest, oral analgesics, and oral caffeine. Blood patch therapy was explained at this time. Comparison of the following variables between the two groups was made with χ^2 analysis with Yates' correction factor when appropriate: incidence of elective and emergency surgery, PDPH, failure to obtain surgical anesthesia, need for intravenous analgesic supplement, paresthesias, shivering, back pain, and use of neuraxial morphine and transdermal scopolamine. A P value <0.05 was considered significant. A two-tailed t-test was used to compare age, height, weight, gravidity, parity, bupivacaine dose, number of days of follow-up, number of attempts to puncture the dura, ephedrine dose, and total volume of intravenous fluid administered. A P value <0.05 was considered significant.

Table 1. Patient Characteristics in the Two Study Groups

	27-Gauge Quincke needle (n = 147)	24-Gauge Sprotte needle (n = 151)
Age (yr)	30.3 ± 5.0	30.5 ± 4.5
Height (cm)	160.8 ± 6.1	161.9 ± 6.5
Weight (kg)	73.7 ± 10.7	75.1 ± 12.9
Gravidity	2.3 ± 1.3	2.4 ± 1.5
Parity	1.0 ± 1.1	1.0 ± 0.9

Mean ± SD.

Table 2. Nonparametric Clinical Variables in the Two Study Groups

	27-Gauge Quincke needle (n = 147)	24-Gauge Sprotte needle (n = 151)
Elective cases	93 (63)	96 (64)
Emergencies	54 (37)	55 (36)
PDPHs	5 (3.5)	1 (<1)
Failures	1 (<1)	0 (0)
Received IV analgesia	23 (16)	19 (13)
Paresthesia at spinal needle insertion	9 (6)	9 (6)
Intraoperative shivering	35 (24)	42 (28)
Postoperative back pain	67 (46)	57 (38)
Intrathecal morphine administered	94 (64)	95 (63)
Transdermal scopolamine patch placed	43 (29)	47 (31)

PDPH, postdural puncture headache; IV, intravenous.
Number of patients (percent).

Table 3. Parametric Clinical Variables in the Two Study Groups

	27-Gauge Quincke needle (n = 147)	24-Gauge Sprotte needle (n = 151)
Bupivacaine dose (mg)	13.6 (1.3)	13.8 (1.2)
Days follow-up	4.6 (0.8)	4.5 (0.8)
Number of attempts at LP	1.7 (1.1)	1.6 (1.0)
Ephedrine administered (mg)	10.6 (10.6)	12.4 (9.5)
Intraoperative IV fluids (mL)	2860 (539)	2889 (552)

LP, lumbar puncture; IV, intravenous.
Mean (± SD).

Results

Demographic data are shown in Table 1 and do not differ significantly between the two groups. Table 2 shows the incidence of elective and emergency surgery, PDPH, failure to obtain surgical anesthesia, need for intravenous analgesic supplement, paresthesias, shivering, back pain, and the use of neuroaxial morphine and transdermal scopolamine. Table 3 compares bupivacaine dose, number of days of follow-up, number of attempts to puncture the dura, ephedrine dose, and total volume of intravenous fluid administered. The incidence of shivering at elective surgery was 20%. The overall incidence of PDPH was 2% (n = 6), one PDPH occurring in the Sprotte group (0.7%) and five in the Quincke group (3.4%). This difference was not statistically significant.

Five of these headaches were classified as mild, and only one was moderate to severe. All recovered quickly with conservative management and without blood patch. Thirty episodes of headache that occurred in the postpartum period did not have the features of PDPH (10% incidence). Thirteen were in the Sprotte group and 17 in the Quincke group. This difference was not significant.

Discussion

Postdural puncture headache after cesarean section remains an important cause of postoperative morbidity. Of note, Chadwick et al. (2), in a review of closed claims in the ASA database, revealed that headaches are the third most frequent reason for claims against anesthesiologists in obstetrics (2). Median payment was $5000 (range $1000–$20,000).

It is accepted that the incidence of PDPH is directly related to needle size (3), but until recently the smallest size of Quincke needle available was 25 gauge. When used for cesarean section, the 25-gauge Quincke needle is associated with a high incidence of PDPH (e.g., 14.5% in a study by Cesarini et al. [1]). This has deterred many from freely adopting spinal anesthesia in obstetrics. The introduction of finer gauge Quincke needles (26-, 27-, 29-, and 30-gauge) has encouraged their evaluation for cesarean section. Puncture with both 29- and 30-gauge Quincke needles is usually performed through another needle placed in the epidural space, and this introduces the possibility of a dural puncture with a larger gauge epidural needle. Although the incidence of associated PDPH is very low, technical difficulties with these very small needles are frequently reported (4). Further experience would no doubt improve results.

The 26-gauge Quincke needle has not been widely studied in obstetrics, but reported PDPH rates have varied considerably (e.g., Barker [5] 2%; Snyder et al. [6] 25%). The 27-gauge Quincke needle is easy to use through an introducer, and spinal fluid returns adequately. Little information is available on the use of this needle in obstetrics.

Focus on the design of the needle tip is not new. In 1923, Greene (7) modified a beveled needle by rounding the tip and further beveling the edge in an effort to reduce dural trauma and PDPH. Hart and Whitacre (8) in 1951 introduced a solid-tip pencil-point needle with a lateral eye, believing that this would spread rather than cut dural fibers, and reported a low incidence of associated PDPH. Now known as the Whitacre needle, it has been available in a 22-gauge size for many years and has its loyal advocates; however, randomized trials comparing it with the Quincke needle were not attempted until recently. Snyder et al. (6) reported a 4% incidence of PDPH after 22-gauge Whitacre needle use, compared with 25% after 26-gauge Quincke needle use. A 25-gauge Whitacre needle is newly available, but its ability to reduce the incidence of PDPH has yet to be fully evaluated. In Sweden, Haraldson (9) in 1951 independently reported on the use of a pencil-point needle designed by Sjövall of very similar appearance to the Whitacre needle.

Sprotte et al. (10) reported in 1987 on a 6-yr experience with 22- and 24-gauge needles of his own design. The tip is solid, ogival in shape, with a lateral eye that is longer than the Whitacre needle eye. The incidence of PDPH was very low (0.02%), but obstetric patients were not included. Cesarini et al. (1) studied the 25-gauge Quincke and 24-gauge Sprotte needles in a randomized trial for cesarean section. No headaches were reported in the Sprotte group, but 14.5% were reported in the Quincke group.

The present study aimed to reduce the number of variables that might affect the incidence of PDPH. The population was entirely obstetric, and the surgery and local anesthetic agent used were standardized. Direct questioning revealed a very low and acceptable incidence of PDPH. There was no significant difference in the incidence of PDPH between the two needle groups with this sample size, although a definite trend was observed in favor of the Sprotte needle. It is possible that a study with a much larger sample size (800–1000 subjects per group) would reveal a significant advantage for the Sprotte needle. It was hoped that an observer questioning the patients would be unaware of which needle had been used. Unfortunately, manpower logistics rendered this impossible, but because objective criteria were used to determine the presence and classification of PDPH, the results should not be biased. It is possible that some patients developed a headache after discharge from the hospital, because no telephone follow-up was done. From a practical standpoint, however, no patient required prolonged hospitalization because of PDPH. A subgroup of patients received transdermal scopolamine (n = 97), and this drug could possibly influence the incidence of headache, although there was no evidence of this. Johnson et al. (11) have suggested that intrathecal fentanyl might lower the incidence of PDPH if added to the local anesthetic at cesarean section. Carney et al. (12) were not able to show that intrathecal morphine diminished the incidence of PDPH after cesarean section. In the present study, headaches only occurred in those who received intrathecal morphine. Although a clear trend was noted, statistical significance was lacking.

The comparative cost of Sprotte and Quincke needles is an important consideration. When purchased in bulk, the cost to the Royal Victoria Hospital in May 1991 was $2.44 CAN for the 27-gauge Quincke needle and $10.00 CAN for the 24-gauge Sprotte needle. There is obviously a considerable cost benefit in using the 27-gauge Quincke needle for routine cases, possibly reserving the Sprotte needle for an anticipated difficult block. The 27-gauge Quincke needle is more flexible, and the backflow of spinal fluid is slower than with the 24-gauge Sprotte needle. Those taking part in the study became adept and comfortable with both needles, but if asked for a subjective judgment, most would prefer the Sprotte. Anesthetic failures have been reported by Crone and Vogel (13) with the Sprotte needle and are thought to be related to the long lateral eye, with injection of some of the local anesthetic into the epidural space. No failures were seen with the Sprotte needle in this series.

The incidence of shivering at elective cesarean section (20%) was much lower in this study than that reported by Workhoeven (14) under epidural anesthesia (64%) with intravenous fluid at room temperature. The impression that less shivering occurs under spinal than under epidural anesthesia deserves further investigation.

Postoperative back pain was present in a surprisingly high number of patients, although the majority of these appeared totally undisturbed by this complaint. Evaluation of the severity and duration of back pain after spinal anesthesia for cesarean section is warranted. Back pain is a common complaint after spinal anesthesia for other types of surgery and may deter a patient from accepting the same anesthetic in the future (15).

In conclusion, spinal anesthesia with either the 24-gauge Sprotte or the 27-gauge Quincke needle was associated with a high degree of satisfaction from patients, anesthetists, and obstetricians and a low (2%) incidence of PDPH.

ecovery and anesthetic control

Significantly less nausea and vomiting than with thiopental/isoflurane

	DIPRIVAN	Thiopental/ isoflurane
Wetchler[2]	(n = 20)	(n = 20)
Nausea/vomiting	20%	65%
Sung et al[3]	(n = 49)	(n = 50)
Nausea/vomiting	8.1%	30%

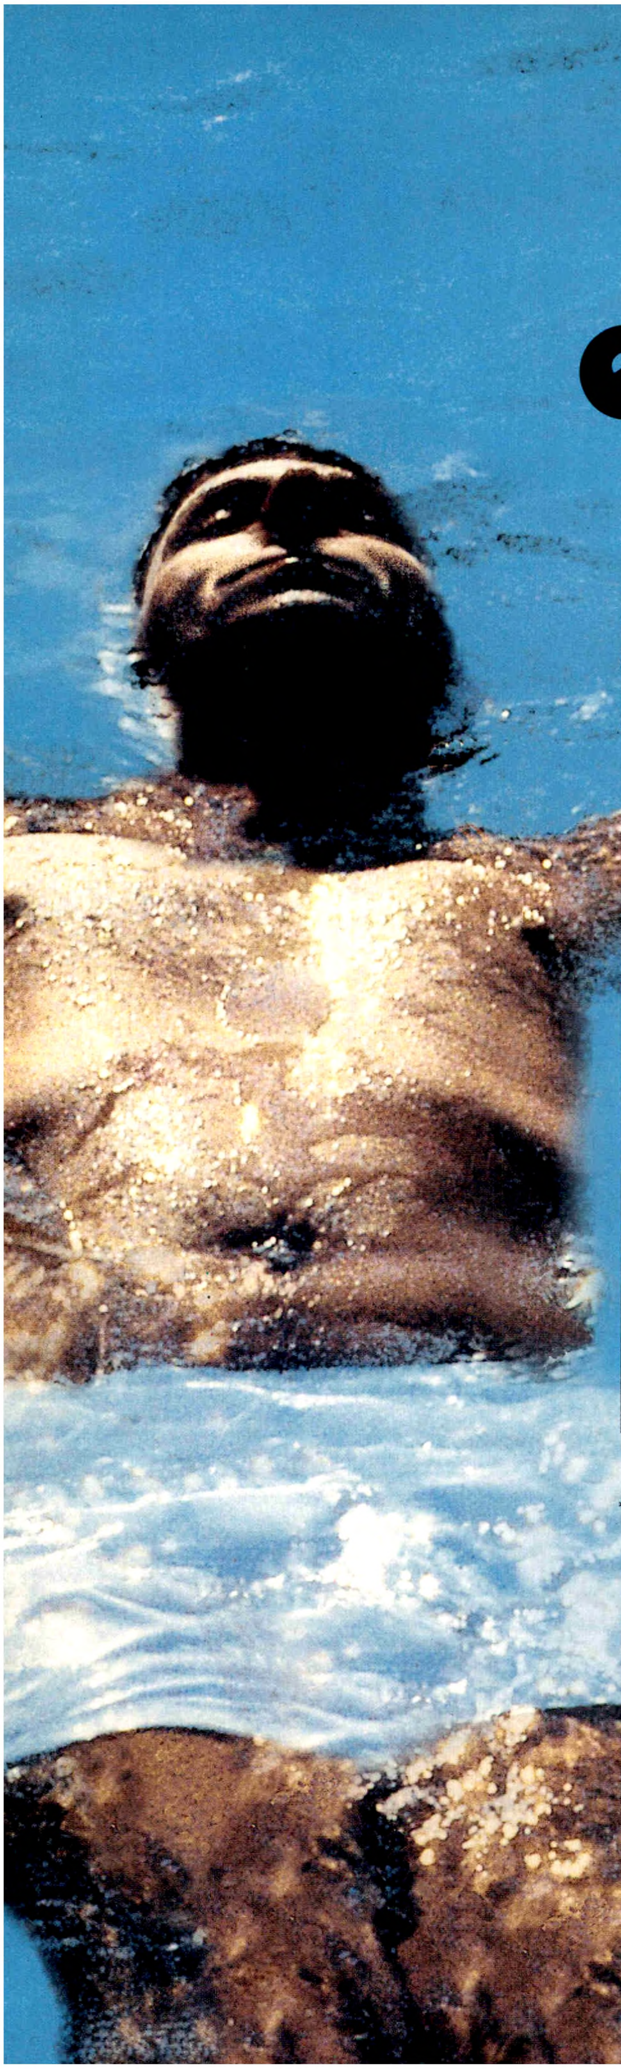
As part of a balanced anesthetic technique, **DIPRIVAN is a cost-effective alternative to thiopental/isoflurane for induction and maintenance.**

Please see last pages of this advertisement for brief summary of prescribing information.

For induction and maintenance

DIPRIVAN®

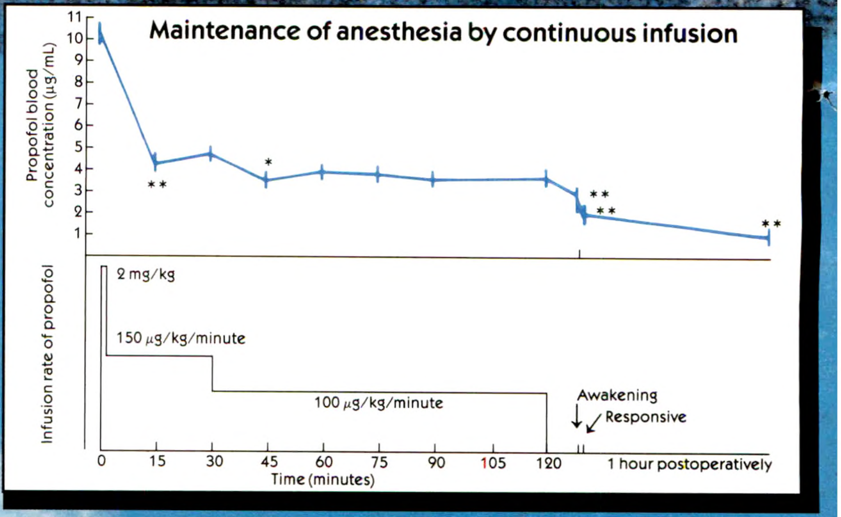
INJECTION propofol



Superior
exceptional

Maintenance of anesthesia as easily controlled as with isoflurane

- Steady state blood concentrations are proportional to rate of administration



—adapted from Herregods et al, p 364[4]

*Significant difference ($P < .05$) from previous value.
**$P < .02$. (Mean and SEM values are shown.)

After a loading dose of 2 mg/kg, anesthesia was maintained with 150 µg/kg/min for 30 minutes—then 100 µg/kg/min for 90 minutes.[4]

- Total body clearance exceeds estimates of hepatic blood flow[5]
- No active metabolites produced

As with most anesthetic agents, clearance rate of DIPRIVAN decreases in elderly patients.

ecovery and
nesthetic control

Hemodynamic effects are controllable and dose-dependent

- Blood pressure (BP) predictably decreases on induction (sometimes >30%) but is within acceptable ranges for healthy individuals*
- Hemodynamic effects during induction are generally more pronounced than with traditional IV induction agents

After initial decreases in BP following induction, hemodynamics return toward baseline

The cardiovascular effects of DIPRIVAN may be increased in patients who have received sedative or narcotic premedications.[†]

DIPRIVAN is not a narcotic agent
When used with N_2O/O_2 for maintenance, supplementation with IV analgesic agents is generally required; muscle relaxants may also be required.

Strict aseptic techniques must always be maintained while handling DIPRIVAN. DIPRIVAN is a single-use parenteral product and contains no antimicrobial preservatives. DIPRIVAN Injection should be prepared for use just prior to initiation of each individual anesthetic procedure. DIPRIVAN Injection should be drawn into sterile syringes immediately after ampules are opened. Administration should commence promptly and be completed within 6 hours after the ampules have been opened.

*Elderly, debilitated, and/or hypovolemic patients, and those rated ASA III/IV, may have more profound adverse cardiovascular responses.

[†] Induction dose requirements may be reduced.

DIPRIVAN® (propofol) Injection

EMULSION FOR IV ADMINISTRATION

(For full prescribing information, see package insert. A Brief Summary follows.)

CLINICAL PHARMACOLOGY—Individualization of Dosage: General: DIPRIVAN Injection is a potent sedative hypnotic agent which provides clinically useful anesthetic and sedative actions depending upon the dose and technique of administration. Important factors to consider include the types of preinduction and concomitant medications, age, ASA physical classification and level of debilitation of the patient, and ultimately, the dose and rate of administration of DIPRIVAN Injection. Individualization of dose and technique will provide a smooth induction and stable maintenance while reducing potential unwanted side effects. Patients with hypovolemia should have fluid-volume deficits corrected prior to administration of DIPRIVAN Injection. **Induction of Anesthesia:** Most adult patients under 55 years of age and classified ASA I or II require 2.0 to 2.5 mg/kg of DIPRIVAN Injection for induction when unpremedicated or when premedicated with oral benzodiazepines or intramuscular opioids. For induction, DIPRIVAN Injection should be titrated (approximately 40 mg every 10 seconds) against the response of the patient until the clinical signs show the onset of anesthesia. As with other sedative hypnotic agents, the amount of intravenous opioid and/or benzodiazepine premedication will influence the response of the patient to an induction dose of DIPRIVAN Injection. It is important to be familiar with and experienced with the intravenous use of DIPRIVAN Injection before treating elderly, debilitated and ASA III or IV patients. Due to the reduced clearance and higher blood levels, most elderly patients require approximately 1.0 to 1.5 mg/kg (approximately 20 mg every 10 seconds) of DIPRIVAN Injection for induction of anesthesia according to their condition and responses. A rapid bolus should not be used as this will increase the likelihood of undesirable cardiorespiratory depression including hypotension, apnea, airway obstruction and/or oxygen desaturation. (See DOSAGE AND ADMINISTRATION.) **Maintenance of Anesthesia:** Anesthesia can be maintained by administering DIPRIVAN Injection by infusion or intermittent IV bolus injection. The patient's clinical response will determine the infusion rate or the amount and frequency of incremental injections. When administering DIPRIVAN Injection by infusion, syringe pumps or volumetric pumps must be used to provide controlled infusion rates. **Continuous Infusion:** DIPRIVAN Injection 100 to 200 µg/kg/min administered in a variable rate infusion with 60%-70% nitrous oxide and oxygen provides anesthesia for patients undergoing general surgery. Maintenance by infusion of DIPRIVAN Injection should immediately follow the induction dose in order to provide satisfactory or continuous anesthesia during the induction phase. During this initial period following the induction dose higher rates of infusion are generally required (150 to 200 µg/kg/min) for the first 10 to 15 minutes. Infusion rates should subsequently be decreased 30%-50% during the first half-hour of maintenance. Changes in vital signs (increases in pulse rate, blood pressure, sweating and/or tearing) that indicate a response to surgical stimulation or lightening of anesthesia may be controlled by the administration of DIPRIVAN Injection 25 mg (2.5 mL) to 50 mg (5.0 mL) incremental boluses and/or by increasing the infusion rate. If vital sign changes are not controlled after a five minute period, other means such as an opioid, barbiturate, vasodilator or inhalation agent therapy should be initiated to control these responses. For minor surgical procedures (ie, body surface) 60%-70% nitrous oxide can be combined with a variable rate DIPRIVAN infusion to provide satisfactory anesthesia. With more stimulating surgical procedures (ie, intra-abdominal) supplementation with analgesic agents should be considered to provide a satisfactory anesthetic and recovery profile. When supplementation with nitrous oxide is not provided, administration rate(s) of DIPRIVAN Injection and/or opioids should be increased in order to provide adequate anesthesia. Infusion rates should always be titrated downward in the absence of clinical signs of light anesthesia until a mild response to surgical stimulation is obtained in order to avoid administration of DIPRIVAN Injection at rates higher than are clinically necessary. Generally, rates of 50 to 100 µg/kg/min should be achieved during maintenance in order to optimize recovery times. **Intermittent Bolus:** Increments of DIPRIVAN Injection 25 mg (2.5 mL) to 50 mg (5.0 mL) may be administered with nitrous oxide in patients undergoing general surgery. The incremental boluses should be administered when changes in vital signs indicate a response to surgical stimulation or light anesthesia. DIPRIVAN Injection has been used with a variety of agents commonly used in anesthesia such as atropine, scopolamine, glycopyrrolate, diazepam, depolarizing and nondepolarizing muscle relaxants, and opioid analgesics, as well as with inhalational and regional anesthetic agents. In the elderly, rapid bolus doses should not be used as this will increase cardiorespiratory effects including hypotension, apnea, airway obstruction and/or oxygen desaturation. Most elderly patients require a reduction of the recommended maintenance rates for healthy adults (< 55 years) to 50 to 100 µg/kg/min (3 to 6 mg/kg/h). **MAC SEDATION:** When DIPRIVAN Injection is administered for sedation, rates of administration should be individualized and titrated to clinical response. In most patients the rates of DIPRIVAN Injection administration will be approximately 25% of those used for maintenance of general anesthesia. During initiation of MAC sedation, slow infusion or slow injection techniques are preferable over rapid bolus administration. During maintenance of MAC sedation, a variable rate infusion is preferable over intermittent bolus dose administration. In the elderly, debilitated and ASA III or IV patients, rapid (single or repeated) bolus dose administration should not be used for MAC sedation. (See WARNINGS.) **A rapid bolus injection can result in undesirable cardiorespiratory depression including hypotension, apnea, airway obstruction and/or oxygen desaturation. Initiation of MAC Sedation:** For initiation of sedation, either an infusion or a slow injection method may be utilized while closely monitoring cardiorespiratory function. With the infusion method, sedation may be initiated by infusing DIPRIVAN Injection at 100 to 150 µg/kg/min (6 to 9 mg/kg/h) for a period of 3 to 5 minutes and titrating to the desired level of sedation while closely monitoring respiratory function. With the slow injection method for initiation, patients will require approximately 0.5 mg/kg administered over 3 to 5 minutes and titrated to clinical responses. When DIPRIVAN Injection is administered slowly over 3 to 5 minutes, most patients will be adequately sedated and the peak drug effect can be achieved while minimizing undesirable cardiorespiratory effects occurring at high plasma levels. In the elderly, debilitated, and ASA III or IV patients, rapid (single or repeated) bolus dose administration should not be used for MAC sedation. (See WARNINGS.) The rate of administration should be over 3-5 minutes and the dosage of DIPRIVAN Injection should be reduced to approximately 80% of the adult dosage in these patients according to their condition, responses, and changes in vital signs. (See DOSAGE AND ADMINISTRATION.) **Maintenance of MAC Sedation:** For maintenance of sedation, a variable rate infusion method is preferable over an intermittent bolus dose method. With the variable rate infusion method, patients will generally require maintenance rates of 25 to 75 µg/kg/min (1.5 to 4.5 mg/kg/h) during the first 10 to 15 minutes of sedation maintenance. Infusion rates should subsequently be decreased over time to 25 to 50 µg/kg/min and adjusted to clinical responses. In titrating to clinical effect, allow approximately 2 minutes for onset of peak drug effect. Infusion rates should always be titrated downward in the absence of clinical signs of light sedation until mild responses to stimulation are obtained in order to avoid sedative administration of DIPRIVAN Injection at rates higher than are clinically necessary. If the intermittent bolus dose method is used, increments of DIPRIVAN Injection 10 mg (1.0 mL) or 20 mg (2.0 mL) can be administered and titrated to desired level of sedation. With the intermittent bolus method of sedation maintenance there is the potential for respiratory depression, transient increases in sedation depth, and/or prolongation of recovery. In the elderly, debilitated, and ASA III or IV patients, rapid (single or repeated) bolus dose administration should not be used for MAC sedation. (See WARNINGS.) The rate of administration and the dosage of DIPRIVAN Injection should be reduced to approximately 80% of the adult dosage in these patients according to their condition, responses, and changes in vital signs. (See DOSAGE AND ADMINISTRATION.) DIPRIVAN Injection can be administered as the sole agent for maintenance of MAC sedation during surgical/diagnostic procedures. When DIPRIVAN sedation is supplemented with opioid and/or benzodiazepine medications, these agents increase the sedative and respiratory effects of DIPRIVAN and may also result in a slower recovery profile. (See PRECAUTIONS, Drug Interactions.) **INDICATIONS AND USAGE:** DIPRIVAN Injection is an IV anesthetic agent that can be used for both induction and/or maintenance of anesthesia as part of a balanced anesthetic technique for inpatient and outpatient surgery. DIPRIVAN Injection, when administered IV as directed, can be used to initiate and maintain monitored anesthesia care (MAC) sedation during diagnostic procedures. DIPRIVAN Injection may also be used for MAC sedation in conjunction with local/regional anesthesia in patients undergoing surgical procedures. (See PRECAUTIONS.) DIPRIVAN Injection is not recommended for use at this time in patients with increased intracranial pressure or impaired cerebral circulation, in obstetrics including cesarean section deliveries, in nursing mothers, and in pediatric patients. **CONTRAINDICATIONS:** DIPRIVAN Injection is contraindicated in patients with a known hypersensitivity to DIPRIVAN Injection or its components, or when general anesthesia or sedation are contraindicated. **WARNINGS:** For general anesthesia or monitored anesthesia care (MAC) sedation, **DIPRIVAN Injection should be administered only by persons trained in the administration of general anesthesia and not involved in the conduct of the surgical/diagnostic procedure. Patients should be continuously monitored and facilities for maintenance of a patent airway, artificial ventilation, and oxygen enrichment and circulatory resuscitation must be immediately available.** In the elderly, debilitated and ASA III or IV patients, rapid (single or repeated) bolus administration should not be used during general anesthesia or MAC sedation in order to minimize undesirable cardiorespiratory depression including hypotension, apnea, airway obstruction and/or oxygen desaturation. MAC sedation patients should be continuously monitored by persons not involved in the conduct of the surgical or diagnostic procedure; oxygen supplementation should be immediately available and provided where clinically indicated; and oxygen saturation should be monitored in all patients. Patients should be continuously monitored for early signs of hypotension, apnea, airway obstruction and/or oxygen desaturation. These cardiorespiratory effects are more likely to occur following rapid initiation (loading) boluses or during supplemental maintenance boluses, especially in the elderly, debilitated and ASA III or IV patients. DIPRIVAN Injection should not be coadministered through the same IV catheter with blood or plasma because compatibility has not been established. In vitro tests have shown that aggregates of the globular component of the emulsion vehicle have occurred with blood/plasma/serum from humans and animals. The clinical significance is not known. **Strict aseptic techniques must always be maintained during handling as DIPRIVAN Injection is a single-use parenteral product and contains no antimicrobial preservatives. The vehicle is capable of supporting rapid growth of microorganisms. (See DOSAGE AND ADMINISTRATION, Handling Procedures.) Failure to follow aseptic handling procedures may result in microbial contamination causing fever, infection/sepsis and/or other adverse consequences which could lead to life-threatening illness. PRECAUTIONS: General:** A lower induction dose and a slower maintenance rate of administration should be used in elderly, debilitated and ASA III or IV patients. (See CLINICAL PHARMACOLOGY—Individualization of Dosage.) Patients should be continuously monitored for early signs of significant hypotension and/or bradycardia. Treatment may include increasing the rate of intravenous fluid, elevation of lower extremities, use of pressor agents, or administration of atropine. Apnea often occurs during induction and may persist for more than 60 seconds. Ventilatory support may be required. Because DIPRIVAN Injection is an emulsion, caution should be exercised in patients with disorders of lipid metabolism such as primary hyperlipoproteinemia, diabetic hyperlipemia, and pancreatitis. The clinical criteria for discharge from the recovery/day surgery area established for each institution should be satisfied before discharge of the patient from the care of the anesthesiologist. When DIPRIVAN Injection is administered to an epileptic patient, there may be a risk of convulsion during the recovery phase. Transient local pain may occur during intravenous injection, which may be reduced by prior injection of IV lidocaine (1.0 mL of a 1% solution). Venous sequelae (phlebitis or thrombosis) have been reported rarely (< 1%). In two well-controlled clinical studies using dedicated intravenous catheters, no instances of venous sequelae were reported up to 14 days following induction. Pain can be minimized if the larger veins of the forearm or antecubital fossa are used. Accidental clinical extravasation and intentional injection into subcutaneous or perivascular tissues of animals caused minimal tissue reaction. Intra-arterial injection in animals did not induce local tissue effects. Accidental intra-arterial injection has been reported in patients, and other than pain, there were no major sequelae. Perioperative myoclonia, rarely including convulsions and opisthotonus, has occurred in a temporal relationship in cases in which DIPRIVAN Injection has been administered. Clinical features of anaphylaxis, which may include bronchospasm, erythema and hypotension, occur rarely following DIPRIVAN Injection administration, although use of other drugs in most instances makes the relationship to DIPRIVAN Injection unclear. There have been reports of pulmonary edema in temporal relationship to the administration of DIPRIVAN Injection, although a causal relationship is unknown. DIPRIVAN Injection has no vagolytic activity and has been associated with reports of bradycardia, occasionally profound, and/or asystole. The intravenous administration of anticholinergic agents (eg, atropine or glycopyrrolate) should be considered to modify potential increases in vagal tone due to concomitant agents (eg, succinylcholine) or surgical stimuli. There have been rare reports of cardiac arrest in temporal relationship to the administration of DIPRIVAN Injection. **Neurosurgical Anesthesia:** Studies to date indicate that DIPRIVAN Injection decreases cerebral blood flow, cerebral metabolic oxygen consumption, and intracranial pressure, and increases cerebrovascular resistance. DIPRIVAN Injection does not seem to affect cerebrovascular reactivity to changes in arterial carbon dioxide tension. Despite these findings, DIPRIVAN Injection is not recommended for use at this time in patients with increased intracranial pressure or impaired cerebral circulation because DIPRIVAN Injection may cause substantial decreases in mean arterial pressure, and consequently, substantial decreases in cerebral perfusion pressure. Further studies are needed to substantiate what happens to intracranial pressure following DIPRIVAN Injection when decreases in mean arterial and cerebral perfusion are prevented by appropriate measures. **Information for Patients:** Patients should be advised that performance of activities requiring mental alertness, such as operating a motor vehicle, or hazardous machinery or signing legal documents may be impaired for some time after general anesthesia or sedation. **Drug Interactions:** The induction dose requirements of DIPRIVAN Injection may be reduced in patients with intramuscular or intravenous premedication, particularly with narcotics (eg, morphine, meperidine, and fentanyl) and combinations of opioids and sedatives (eg, benzodiazepines, barbiturates, chloral hydrate, droperidol, etc.). These agents may increase the anesthetic or sedative effects of DIPRIVAN Injection and may also result in more pronounced decreases in systolic, diastolic, and mean arterial pressures and cardiac output. During maintenance of anesthesia or sedation, the rate of DIPRIVAN Injection administration should be adjusted according to the desired level of anesthesia or sedation and may be reduced in the presence of supplemental analgesic agents (eg, nitrous oxide or opioids). The concurrent administration of potent inhalational agents (eg, isoflurane, enflurane, and halothane) during maintenance with DIPRIVAN Injection has not been extensively evaluated. These inhalational agents can also be expected to increase the anesthetic or sedative and cardiorespiratory effects of DIPRIVAN Injection. DIPRIVAN Injection does not cause a clinically significant change in onset, intensity or duration of action of the commonly used neuromuscular blocking agents (eg, succinylcholine and nondepolarizing muscle relaxants). No significant adverse interactions with commonly used premedications or drugs used during anesthesia or sedation (including a range of muscle relaxants, inhalational agents, analgesic agents, and local anesthetic agents) have been observed. **Carcinogenesis, Mutagenesis, Impairment of Fertility:** Animal carcinogenicity studies have not been performed with propofol. In vitro and in vivo animal tests failed to show any potential for mutagenicity by propofol. Tests for mutagenicity included the Ames (using *Salmonella* sp) mutation test, gene mutation/gene conversion using *Saccharomyces cerevisiae*, in vitro cytogenetic studies in Chinese hamsters and a mouse micronucleus test. Studies in female rats at intravenous doses up to 15 mg/kg/day (6 times the maximum recommended human induction dose) for 2 weeks before pregnancy to day 7 of gestation did not show impaired fertility. Male fertility in rats was not affected in a dominant lethal study at intravenous doses up to 15 mg/kg/day for 5 days. **Pregnancy Category B:** Reproduction studies have been performed in rats and rabbits at intravenous doses of 15 mg/kg/day (6 times the recommended human induction dose) and have revealed no evidence of impaired fertility or harm to the fetus due to propofol. Propofol, however, has been shown to cause maternal deaths in rats and rabbits and decreased pup survival during the lactating period in dams treated with 15 mg/kg/day (or 6 times the recommended human induction dose). The pharmacological activity (anesthesia) of the drug on the mother is probably responsible for the adverse effects seen in the offspring. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human responses, this drug should be used during pregnancy only if clearly needed. **Labor and Delivery:** DIPRIVAN Injection is not recommended for obstetrics, including cesarean section deliveries. DIPRIVAN Injection crosses the placenta, and as with other general anesthetic agents, the administration of DIPRIVAN Injection may be associated with neonatal depression. **Nursing Mothers:** DIPRIVAN Injection is not recommended for use in nursing mothers because DIPRIVAN has been reported to be excreted in human milk and the effects of oral absorption of small amounts of propofol are not known. **Pediatric Use:** DIPRIVAN Injection is not recommended for use in pediatric patients because safety and effectiveness have not been established. **ADVERSE REACTIONS:** Adverse event information is derived from controlled clinical trials and worldwide marketing experience. In the description below, rates of the more common events represent US/Canadian clinical study results. Less frequent events are derived principally from publications and marketing experience in over 8 million patients; there are insufficient data to support an accurate estimate of their incidence rates. The adverse experience profile from reports of 150 patients in the US/Canadian MAC sedation clinical trials is similar to the profile established with DIPRIVAN Injection during anesthesia (see below). During MAC sedation clinical trials, significant respiratory events included cough, upper airway obstruction, apnea, hypoventilation, and dyspnea. The most common adverse events which occurred in more than 3% of the patients receiving DIPRIVAN Injection for MAC sedation included hypotension, nausea, headache, and injection site pain or hotness. The following estimates of adverse events for DIPRIVAN Injection are derived from reports of 2588 patients included in the US/Canadian studies. These studies were conducted using a variety of premedicants, varying lengths of surgical/diagnostic procedures and various other anesthetic/sedative agents. Most adverse events were mild and transient. The following adverse events were reported in patients treated with DIPRIVAN Injection. They are presented within each body system in order of decreasing frequency. **Incidence Greater than 1%—All events regardless of causality, derived from clinical trials. Body as a Whole:** Fever. **Cardiovascular:** Hypotension* (see also CLINICAL PHARMACOLOGY), Bradycardia, Hypertension, Arrhythmia. **Central Nervous System:** Movement*, Headache, Dizziness, Twitching. **Digestive:** Nausea** (15%), Vomiting*, Abdominal Cramping. **Injection Site:** Pain*, Burning/Stinging*. **Respiratory:** Hiccough, Cough (see also CLINICAL PHARMACOLOGY). **Skin and Appendages:** Rash. Incidence of unmarked events is 1%-3%; *3% to 9%; **10% or greater. **Incidence Less than 1%—Causal Relationship Probable, derived from clinical trials.** (Adverse events reported in the literature, not seen in clinical trials, are *italicized*.) **Body as a Whole:** Perinatal Disorder, Extremities Pain, Awareness, Chest Pain, Increased Drug Effect, Neck Rigidity/Stiffness, Trunk Pain. *Anaphylaxis/Anaphylactoid Reaction.* **Cardiovascular:** Tachycardia, Premature Ventricular Contractions, Syncope, Premature Atrial Contractions, Abnormal ECG, ST Segment Depression, Bundle Branch Block, Extrasystole, Myocardial Infarction, Heart Block, Atrioventricular Block, Second Degree A-V Block. **Central Nervous System:** Bucking/Jerking/Thrashing, Clonic/Myoclonic Movement, Hypertonia/Dystonia, Chills/Shivering, Somnolence, Tremor, Agitation, Confusion, Delirium, Paresthesia, Abnormal Dreams, Euphoria, Fatigue, Moaning, Rigidity, Combativeness, Depression. **Digestive:** Hypersalivation, Dry Mouth, Swallowing, Enlarged Parotid. **Injection Site:** Tingling/Numbness, Coldness, Discomfort, Phlebitis, Hives/Itching, Redness/Discoloration. **Metabolic/Nutritional:** Hyperlipemia. **Musculoskeletal:** Myalgia. **Respiratory:** Apnea (see also CLINICAL PHARMACOLOGY), Upper Airway Obstruction, Wheezing, Dyspnea, Hypoventilation, Bronchospasm, Burning in Throat, Sneezing, Tachypnea, Hyperventilation, Hypoxia, Pharyngitis. **Skin and Appendages:** Flushing, Urticaria, Pruritus. **Special Senses:** Amblyopia, Diplopia, Taste Perversion, Eye Pain, Tinnitus. **Urogenital:** Abnormal Urine, Urine Retention, *Green Urine*. **Incidence Less than 1%—Causal Relationship Unknown, derived from clinical trials.** (Adverse events reported in the literature, not seen in clinical trials, are *italicized*.) **Body as a Whole:** Asthenia. **Cardiovascular:** Atrial Fibrillation, Bigeminy, Hemorrhage, Edema, Ventricular Fibrillation, Supraventricular Tachycardia, *Myocardial Ischemia*. **Central Nervous System:** Emotional Lability, Anxiety, Hysteria, Insomnia, Generalized and Localized Seizures, *Opisthotonus, Hypotonia, Hallucinations, Neuropathy, Thinking Abnormal.* **Digestive:** Diarrhea. **Hematologic/Lymphatic:** Coagulation Disorder. **Metabolic/ Nutritional:** Hyperkalemia. **Respiratory:** Laryngospasm. **Skin and Appendages:** Diaphoresis, *Conjunctival Hyperemia*. **Special Senses:** Ear Pain, *Nystagmus*. **Urogenital:** Oliguria. In addition to those adverse events listed above, the following adverse event has been reported as a result of postmarketing experience: amorous behavior. **DOSAGE AND ADMINISTRATION:** Dosage and rate of administration should be individualized and titrated to the desired effect according to clinically relevant factors including preinduction and concomitant medications, age, ASA physical classification and level of debilitation of the patient. The following is abbreviated dosage and administration information which is only intended as a general guide in the use of DIPRIVAN Injection. Prior to administering DIPRIVAN Injection, it is imperative that the physician review and be completely familiar with the specific dosage and administration information detailed in the CLINICAL PHARMACOLOGY—Individualization of Dosage section. In the elderly, debilitated and ASA III or IV patients, rapid bolus doses should not be used in the methods of administration described below. (See WARNINGS.)**

Induction of Anesthesia	Dosage should be individualized and titrated. **Adults*:** Most patients require 2.0 to 2.5 mg/kg (approximately 40 mg every 10 seconds until induction onset). **Elderly, Debilitated and ASA III or IV Patients:** Most patients require 1.0 to 1.5 mg/kg (approximately 20 mg every 10 seconds until induction onset). For complete dosage information, see CLINICAL PHARMACOLOGY—Individualization of Dosage.
Maintenance of Anesthesia: Infusion	Variable rate infusion—titrated to the desired clinical effect. **Adults*:** Most patients require 100 to 200 µg/kg/min (6 to 12 mg/kg/h). **Elderly, Debilitated and ASA III or IV Patients:** Most patients require 50 to 100 µg/kg/min (3 to 6 mg/kg/h).
Maintenance of Anesthesia: Intermittent Bolus	Increments of 25 mg to 50 mg as needed. For complete dosage information, see CLINICAL PHARMACOLOGY—Individualization of Dosage.
Initiation of MAC Sedation	Dosage and rate should be individualized. **Adults*:** Slow infusion or slow injection techniques are preferable over rapid bolus administration. Most patients require an infusion of 100 to 150 µg/kg/min (6 to 9 mg/kg/h) or a slow injection of 0.5 mg/kg over 3 to 5 minutes. **Elderly, Debilitated and ASA III or IV Patients:** Most patients require dosages similar to adults, but must be given as a slow infusion or slow injection and not as a rapid bolus. (See WARNINGS.)
Maintenance of MAC Sedation	Dosage and rate should be titrated to clinical effect. **Adults*:** A variable rate infusion technique is preferable over an intermittent bolus technique. Most patients require an infusion of 25 to 75 µg/kg/min (1.5 to 4.5 mg/kg/h) or incremental bolus doses of 10 mg or 20 mg. **Elderly, Debilitated and ASA III or IV Patients:** Most patients require a 20% reduction of the adult dose. A rapid (single or repeated) bolus dose should not be used. (See WARNINGS.) For complete dosage information, see CLINICAL PHARMACOLOGY—Individualization of Dosage.

*Adults—healthy, less than 55 years of age

Handling Procedures: Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit. DIPRIVAN Injection must not be administered through filters with a pore size less than 5 µm because this could restrict the flow of DIPRIVAN and/or cause the breakdown of the emulsion. Do not use if there is evidence of separation of the phases of the emulsion. **Strict aseptic techniques must always be maintained during handling as DIPRIVAN Injection is a single-use parenteral product and contains no antimicrobial preservatives. The vehicle is capable of supporting rapid growth of microorganisms. Failure to follow aseptic handling procedures may result in microbial contamination causing fever, infection/sepsis and/or other adverse consequences which could lead to life-threatening illness.** DIPRIVAN Injection should be prepared for use just prior to initiation of each individual anesthetic/sedative procedure. The ampule neck surface or vial rubber stopper should be disinfected using 70% isopropyl alcohol. DIPRIVAN Injection should be drawn into sterile syringes immediately after ampules or vials are opened. When withdrawing DIPRIVAN Injection from vials, a sterile vent spike should be used. The syringe(s) should be labeled with appropriate information including the date and time the ampule or vial was opened. Administration should commence promptly and be completed within 6 hours after the ampules or vials have been opened. DIPRIVAN Injection should be prepared for single patient use only. Any unused portions of DIPRIVAN Injection, reservoirs, dedicated administration tubing and/or solutions containing DIPRIVAN Injection must be discarded at the end of the anesthetic procedure or at 6 hours, whichever occurs sooner. The IV line should be flushed every 6 hours and at the end of the anesthetic procedure to remove residual DIPRIVAN Injection.

Shake well before use. Rev B 03/92

ANESTHESIA INTENSIVISTS

The UMDNJ—Robert Wood Johnson Medical School is recruiting for two Anesthesia Intensivists for the Department of Anesthesia to be Co-Directors of the Surgical Intensive Care Unit at Robert Wood Johnson University Hospital. This 20 station modern unit is expanding to 27 stations in our 416 bed tertiary care facility, located in Central New Jersey. Academic rank and salary will be commensurate with qualifications.

Send cover letter, CV, and 3 letters of reference to: **Sanford L. Klein, D.D.S., M.D., Chairman, Department of Anesthesia, UMDNJ - Robert Wood Johnson Medical School, 1 Robert Wood Johnson Place, CN 19, New Brunswick, NJ 08903-0019.** UMDNJ, New Jersey's university of the health sciences, is an Affirmative Action/Equal Employment Opportunity Employer, m/f/h/v, and a member of the University Health System of New Jersey.

UMD
NEW JERSEY

Level I Trauma Center
ANESTHESIOLOGIST

A major emergency/trauma center in metropolitan Detroit has an immediate opening for an anesthesiologist with an interest in trauma. The position is part of a physician/certified registered nurse anesthetist practice at Detroit Receiving Hospital and University Health Center, a Level I trauma center verified by the American College of Surgeons. Detroit Receiving is affiliated with the Wayne State University School of Medicine.

An excellent compensation package is available, including paid malpractice, health, dental, life insurance and other benefits. Send C.V. to: Samuel Perov, M.D. Chief of Anesthesiology, Detroit Receiving Hospital and University Health Center, 4201 St. Antoine, Detroit, Michigan, 48201.

THE SYNERGY OF CO-INDUCTION

Optimal induction produces 1) unconsciousness and 2) a rapid progression to a state of anesthesia, with maintenance of stable cardiovascular functioning.[1]

However, even though high doses of hypnotics—such as thiopental or propofol—can achieve both endpoints, they can also cause significant hemodynamic changes. Therefore, it may be advantageous to manage hypnosis and anesthesia sequentially by employing a combination of function-specific agents.

Indeed, VERSED given in combination with a second agent can achieve hypnosis through the synergistic interaction of subanesthetic doses,[2-8] the goal being to maximize desired effects and reduce the undesired.

The advantage of co-induction

It is well established that induction agents potentiate each other when given in combination. One quarter of the hypnotic ED_{50} of VERSED can reduce the hypnotic ED_{50} of thiopental by as much as 75%.[3]

However, this degree of reduction occurs when thiopental is given one minute after VERSED, thereby achieving synchronous peak effects. The magnitude of interaction diminishes as the interval between the administration of the co-induction agents lengthens.

Dosing considerations with VERSED® (midazolam HCl/Roche) (IV)

When VERSED is used before other intravenous agents for induction of anesthesia, the initial dose of each agent may be significantly reduced, at times to as low as 25% of the usual initial dose of the individual agents.

As a standard precaution, prior to I.V. administration of VERSED in any dose, oxygen and resuscitative equipment should be immediately available. VERSED should be used as an induction agent only by persons trained in anesthesiology and who are familiar with all dosing and administration guidelines. Reduce dosage in elderly or debilitated patients, in patients receiving narcotic premedication and in those with limited pulmonary reserve.

It is recommended that patients do not drive or operate hazardous machinery after receiving VERSED until the effects of the drug (*e.g.*, drowsiness) are gone or until the day after anesthesia, whichever is longer. The decision must be individualized.

VERSED®
midazolam HCl/Roche ℂ
INJECTION

Before prescribing, please consult complete product information, a summary of which follows:

> Intravenous VERSED has been associated with respiratory depression and respiratory arrest, especially when used for conscious sedation. In some cases, where this was not recognized promptly and treated effectively, death or hypoxic encephalopathy has resulted. Intravenous VERSED should be used only in hospital or ambulatory care settings, including physicians' offices, that provide for continuous monitoring of respiratory and cardiac function. Immediate availability of resuscitative drugs and equipment and personnel trained in their use should be assured. (See WARNINGS.)
>
> The initial intravenous dose for conscious sedation may be as little as 1 mg, but should not exceed 2.5 mg in a normal healthy adult. Lower doses are necessary for older (over 60 years) or debilitated patients and in patients receiving concomitant narcotics or other CNS depressants. The initial dose and all subsequent doses should never be given as a bolus; administer over at least 2 minutes and allow an additional 2 or more minutes to fully evaluate the sedative effect. The use of the 1 mg/mL formulation or dilution of the 1 mg/mL or 5 mg/mL formulation is recommended to facilitate slower injection. Consult complete product information under DOSAGE AND ADMINISTRATION for complete dosing information.

CONTRAINDICATIONS: Patients with known hypersensitivity to the drug.

Benzodiazepines are contraindicated in patients with acute narrow angle glaucoma; may be used in open angle glaucoma only if patients are receiving appropriate therapy.

Not intended for intrathecal or epidural administration due to the presence of the preservative benzyl alcohol.

WARNINGS: Never use without individualization of dosage. Prior to IV use in any dose, ensure immediate availability of oxygen, resuscitative equipment and skilled personnel for maintenance of a patent airway and support of ventilation. Continuously monitor for early signs of underventilation or apnea, which can lead to hypoxia/cardiac arrest unless effective countermeasures are taken immediately. Vital signs should continue to be monitored during the recovery period.

Because IV VERSED depresses respiration, and opioid agonists and other sedatives can add to this depression, it should be administered as an induction agent only by a person trained in general anesthesia and should be used for conscious sedation only in the presence of personnel skilled in early detection of underventilation, maintaining a patent airway and supporting ventilation. **For conscious sedation, do not administer IV by rapid or single bolus.** Serious cardiorespiratory adverse events have occurred. These have included respiratory depression, apnea, respiratory arrest and/or cardiac arrest, sometimes resulting in death. There have been rare reports of hypotensive episodes requiring treatment during or after diagnostic or surgical manipulations in patients who have received VERSED. Hypotension occurred more frequently in the conscious sedation studies in patients premedicated with narcotic.

Reactions such as agitation, involuntary movements, hyperactivity and combativeness have been reported. These may be due to inadequate or excessive dosing or improper administration; however, the possibility of cerebral hypoxia or true paradoxical reactions should be considered. Should these reactions occur, response to each dose of VERSED and all other drugs should be evaluated before proceeding.

Concomitant use of barbiturates, alcohol or other CNS depressants may increase the risk of underventilation or apnea and may contribute to profound and/or prolonged drug effect. Narcotic premedication also depresses the ventilatory response to carbon dioxide stimulation.

Higher risk surgical, elderly or debilitated patients require lower dosages for induction of anesthesia, premedicated or not. Patients with chronic obstructive pulmonary disease are unusually sensitive to the respiratory depressant effect of VERSED. Patients with chronic renal failure and patients with congestive heart failure eliminate midazolam more slowly. Because elderly patients frequently have inefficient function of one or more organ systems, and because dosage requirements have been shown to decrease with age, reduce initial dosage and consider possibility of a profound and/or prolonged effect.

Do not administer in shock, coma, acute alcohol intoxication with depression of vital signs. Particular care should be exercised in the use of IV VERSED in patients with uncompensated acute illnesses, such as severe fluid or electrolyte disturbances.

Guard against unintended intra-arterial injection; hazards in humans unknown. Avoid extravasation.

VERSED should only be administered IM or IV. Safety and efficacy of other routes of administration are not established.

Gross tests of recovery from the effects of VERSED cannot alone predict reaction time under stress. This drug is never used alone during anesthesia, and the contribution of other perioperative drugs and events can vary. The decision as to when patients may engage in activities requiring mental alertness must be individualized; it is recommended that no patient should operate hazardous machinery or a motor vehicle until the effects of the drug, such as drowsiness, have subsided or until the day after anesthesia, whichever is longer.

Usage in Pregnancy: An increased risk of congenital malformations associated with the use of benzodiazepines (diazepam and chlordiazepoxide) has been suggested in several studies. If VERSED is used during pregnancy, apprise the patient of the potential hazard to the fetus.

PRECAUTIONS: *General:* Decrease intravenous doses in elderly and debilitated patients. These patients will also probably take longer to recover completely after VERSED for induction of anesthesia.

VERSED does not protect against increased intracranial pressure or against the heart rate rise and/or blood pressure rise associated with endotracheal intubation under light general anesthesia.

Information for patients: Communicate the following information and instructions to the patient when appropriate: 1. Inform your physician about any alcohol consumption and medicine you are now taking, including nonprescription drugs. Alcohol has an increased effect when consumed with benzodiazepines; therefore, caution should be exercised regarding simultaneous ingestion of alcohol and benzodiazepines. 2. Inform your physician if you are pregnant or are planning to become pregnant. 3. Inform your physician if you are nursing.

Drug interactions: The sedative effect of IV VERSED is accentuated by premedication,

particularly narcotics (*e.g.*, morphine, meperidine, fentanyl) and also secobarbital and Innovar (fentanyl and droperidol). Consequently, adjust the dosage according to the type and amount of premedication.

A moderate reduction in induction dosage requirements of thiopental (about 15%) has been noted following use of IM VERSED for premedication.

IV administration of VERSED decreases the minimum alveolar concentration (MAC) of halothane required for general anesthesia. This decrease correlates with the dose of VERSED administered.

Although the possibility of minor interactive effects has not been fully studied, VERSED and pancuronium have been used together in patients without noting clinically significant changes in dosage, onset or duration. VERSED does not protect against the characteristic circulatory changes noted after administration of succinylcholine or pancuronium, or against the increased intracranial pressure noted following administration of succinylcholine. VERSED does not cause a clinically significant change in dosage, onset or duration of a single intubating dose of succinylcholine.

No significant adverse interactions with commonly used premedications or drugs used during anesthesia and surgery (including atropine, scopolamine, glycopyrrolate, diazepam, hydroxyzine, d-tubocurarine, succinylcholine and nondepolarizing muscle relaxants) or topical local anesthetics (including lidocaine, dyclonine HCl and Cetacaine) have been observed.

Clearance of midazolam and certain other benzodiazepines may be delayed with concomitant administration of cimetidine (but not ranitidine). Clinical significance of this interaction is unclear.

Drug/laboratory test interactions: Midazolam has not been shown to interfere with clinical laboratory test results.

Carcinogenesis, mutagenesis, impairment of fertility: Midazolam maleate was administered to mice and rats for two years. At the highest dose (80 mg/kg/day) female mice had a marked increase in incidence of hepatic tumors and male rats had a small but significant increase in benign thyroid follicular cell tumors. These tumors were found after chronic use, whereas human use will ordinarily be of single or several doses.

Midazolam did not have mutagenic activity in tests that were conducted.

A reproduction study in rats did not show any impairment of fertility at up to ten times the human IV dose.

Pregnancy: Teratogenic effects: Pregnancy Category D. See WARNINGS section.

Midazolam maleate injectable, at 5 and 10 times the human dose, did not show evidence of teratogenicity in rabbits and rats.

Labor and delivery: Use in obstetrics has not been evaluated. Because midazolam is transferred transplacentally and because other benzodiazepines given in the last weeks of pregnancy have resulted in neonatal CNS depression, VERSED is not recommended for obstetrical use.

Nursing mothers: Excreted in human milk. Not recommended for use in nursing mothers.

Pediatric use: Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS: See WARNINGS concerning serious cardiorespiratory events and possible paradoxical reactions. Fluctuations in vital signs following parenteral administration were the most frequently seen findings and included decreased tidal volume and/or respiratory rate decrease (23.3% of patients following IV and 10.8% of patients following IM administration) and apnea (15.4% of patients following IV administration), as well as variations in blood pressure and pulse rate.

Following IM injection: headache (1.3%); local effects at IM site: pain (3.7%), induration (0.5%), redness (0.5%), muscle stiffness (0.3%).

IM administration to elderly and/or high-risk surgical patients has been associated with rare reports of death under circumstances compatible with cardiorespiratory depression. In most of these cases, patients also received other CNS depressants capable of depressing respiration, especially narcotics.

Following IV administration: hiccoughs (3.9%), nausea (2.8%), vomiting (2.6%), coughing (1.3%), "oversedation" (1.6%), headache (1.5%), drowsiness (1.2%); local effects at the IV site: tenderness (5.6%), pain during injection (5.0%), redness (2.6%), induration (1.7%), phlebitis (0.4%). Other effects (<1%) mainly following IV administration: *Respiratory:* Laryngospasm, bronchospasm, dyspnea, hyperventilation, wheezing, shallow respirations, airway obstruction, tachypnea. *Cardiovascular:* Bigeminy, premature ventricular contractions, vasovagal episode, bradycardia, tachycardia, nodal rhythm. *Gastrointestinal:* Acid taste, excessive salivation, retching. *CNS/Neuromuscular:* Retrograde amnesia, euphoria, hallucination, confusion, argumentativeness, nervousness, anxiety, grogginess, restlessness, emergence delirium or agitation, prolonged emergence from anesthesia, dreaming during emergence, sleep disturbance, insomnia, nightmares, athetoid movements, seizure-like activity, ataxia, dizziness, dysphoria, slurred speech, dysphonia, paresthesia. *Special Sense:* Blurred vision, diplopia, nystagmus, pinpoint pupils, cyclic movements of eyelids, visual disturbance, difficulty focusing eyes, ears blocked, loss of balance, lightheadedness. *Integumentary:* Hive-like elevation at injection site, swelling or feeling of burning, warmth or coldness at injection site. *Hypersensitivity:* Allergic reactions, including anaphylactoid reactions, hives, rash, pruritus. *Miscellaneous:* Yawning, lethargy, chills, weakness, toothache, faint feeling, hematoma.

Drug Abuse and Dependence: Available data concerning the drug abuse and dependence potential of midazolam suggest that its abuse potential is at least equivalent to that of diazepam.

OVERDOSAGE: Manifestations would resemble those observed with other benzodiazepines (*e.g.*, sedation, somnolence, confusion, impaired coordination, diminished reflexes, coma, untoward effects on vital signs). No specific organ toxicity would be expected.

DOSAGE AND ADMINISTRATION: VERSED is a potent sedative agent which requires slow administration and individualization of dosage. Clinical experience has shown VERSED to be 3 to 4 times as potent per mg as diazepam. BECAUSE SERIOUS AND LIFE-THREATENING CARDIORESPIRATORY ADVERSE EVENTS HAVE BEEN REPORTED, PROVISION FOR MONITORING, DETECTION AND CORRECTION OF THESE REACTIONS MUST BE MADE FOR EVERY PATIENT TO WHOM VERSED INJECTION IS ADMINISTERED, REGARDLESS OF AGE OR HEALTH STATUS. Excess doses or rapid or single bolus intravenous administration may result in respiratory depression and/or arrest. (See WARNINGS.) Prior to use refer to the DOSAGE AND ADMINISTRATION section in the complete product information.

IARS MEMBERSHIP

FOR YOUR IN-TRAINING AND CONTINUING MEDICAL EDUCATION

The International Anesthesia Research Society is a nonprofit, scientific and educational corporation of the State of Ohio, founded in 1922 "to foster progress and research in anesthesia." To this end, the IARS

Publishes the oldest journal in the specialty, *Anesthesia & Analgesia*

Sponsors an annual scientific meeting (Congress) which is held in March

Funds projects in anesthesia-related research, clinical care, education, and administration through the B.B. Sankey Anesthesia Advancement Award, and the Ben Covino Research Award

Membership in the IARS is voluntary; it is also separate and distinct from membership in any other local, state, or national anesthesia organization. Membership is open to individuals who qualify in the various categories shown below. All memberships include a monthly subscription to *Anesthesia & Analgesia* which includes the abstract supplement and the Review Course Lectures Book. Members and Associate Members are entitled to a reduced registration fee at the IARS annual Congress, Educational Members pay no registration fee. Only IARS members may apply for the B.B. Sankey Anesthesia Advancement Award.

MEMBERSHIP CATEGORIES

MEMBERSHIP: Open to individuals with doctorate degrees who are licensed to practice in the medical, osteopathic, dental, or veterinary medicine fields (i.e., MD, MB, DO, DDS, DVM); and to individuals with doctorate degrees (PhD) in any scientific discipline who are engaged in academic, private, or commercial research.

ASSOCIATE MEMBERSHIP: Open to individuals in the allied health professions who are certified by their professional accrediting organization as nurse anesthetists (CRNA), respiratory therapists or technicians (RRT or CRTT), physician assistants (PA, MMS), and other allied health professionals in anesthesia-related practice.

Beginning with the January 1993 issue of *Anesthesia & Analgesia*, International Members will receive the Journal by Surface Air Lift (First Class to Canada) **at no additional charge.**

Annual (1992 Calendar Year) Dues for Members and Associate Members: $95 ($120 Int'l).

Annual (1993 Calendar Year) Dues for Members and Associate Members: $100.

EDUCATIONAL MEMBERSHIP: Open (with certification by program director) to doctors (interns/residents) enrolled in anesthesiology training programs; nurses enrolled in nurse anesthesia schools; students enrolled in programs leading to certification as physician assistants, respiratory therapists, or technicians.

Annual Dues for Educational Members:

2 Years beginning July 1992—$108 ($120 Int'l)	2 Years beginning January 1993—$110	NO POSTAGE SURCHARGE BEGINNING IN 1993
3 Years beginning July 1992—$163 ($175 Int'l)	3 Years beginning January 1993—$165	
4 Years beginning July 1992—$218 ($230 Int'l)	4 Years beginning January 1993—$220	

International Anesthesia Research Society
Suite 140, 2 Summit Park Drive, Cleveland, Ohio 44131-2553

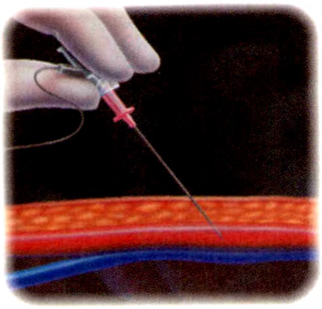
It Took Millions Of Years To Develop This Guidance System.

You'll Appreciate Its Accuracy In Seconds.



Only SmartNeedle guides your needle straight to its mark with the speed of sound.

Whether your target is a femoral, subclavian or internal jugular vessel, you'll be able to distinguish arteries from veins by the sounds SmartNeedle transmits.

Continuous auditory feedback helps you locate the vessel with pinpoint accuracy, puncture it and optimize the needle position within the vessel.

Proven Doppler technology helps your needle find its target while minimizing trauma and complications associated with multiple punctures. Therefore, less time is spent in preparation and patient care can begin without unnecessary delay.

It's easy to see, and hear, why SmartNeedle is essential in the OR, ER, ICU, specials and cath labs. And using it is as easy as it sounds.

What's more, our dedicated service and support are your assurance that it will always be a device you can rely on.

Call 1-800-548-1994 today for more information or to request a demonstration. And get your hands on the technological alternative to flying blind.

***Smart*Needle**™

Pinpoint Accuracy With The Speed Of Sound.™

Peripheral Systems Group

A Division of ACS® 1395 Charleston Rd., Mountain View, CA 94043

SmartNeedle is a registered trademark of Peripheral Systems Group.

SmartNeedle Vascular Access Guidance System designed in conjunction with Paul G. Yock, M.D. This product is intended for use by or under the direction of a physician. Prior to use, it is important to read the package insert thoroughly for instructions on use, warnings and potential complications associated with the use of this device. Manufactured under the following patent: United States, 4,887,606. Other U.S. and foreign patents pending. ©1992 Peripheral Systems Group

A specific reversal agent for benzodiazepine sedation

- MAZICON (flumazenil/Roche) rapidly and specifically reverses sedation produced by any benzodiazepine
- Promptly restores patients to consciousness—often within minutes of reaching an effective dose
- Reverses benzodiazepine sedative effects only—not the effects of narcotics or other CNS agents

Adverse effects

The most common side effects in clinical trials were nausea and vomiting (11%), dizziness (10%), agitation (3-9%) and injection-site pain (3-9%).

Wake Up Call for Benzodiazepine Sedation

Seizures

MAZICON is associated with seizures, most often in patients on benzodiazepines for long-term sedation or patients showing signs of serious cyclic antidepressant overdose. Practitioners should individualize the dosage and be prepared to manage seizures.

Important safety information

Contraindicated in hypersensitivity to benzodiazepines or MAZICON; in patients taking benzodiazepines for control of potentially life-threatening conditions; and in patients showing signs of serious cyclic antidepressant overdose. In patients who are dependent on benzodiazepines, MAZICON may precipitate withdrawal syndromes.

Patients should be monitored for possible resedation, respiratory depression or other residual benzodiazepine effects for an appropriate period based on the dose and duration of effect of the benzodiazepine employed. The availability of MAZICON does not diminish the need for prompt detection of hypoventilation and the need to be prepared to effectively intervene by establishing an airway and assisting ventilation. MAZICON has not been established as an effective treatment for benzodiazepine-induced hypoventilation.

Available in 5-mL and 10-mL vials.

0.1 mg/mL
mazicon I.V.™
flumazenil/Roche

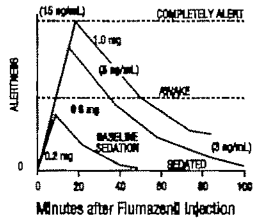
The reversal agent you've been waiting for

MAZICON™
(flumazenil/Roche)
INJECTION

DESCRIPTION: MAZICON™ (flumazenil/Roche) is a benzodiazepine receptor antagonist. Chemically, flumazenil is ethyl 8-fluoro-5,6-dihydro-5-methyl-6-oxo-4H-imidazo[1,5-a](1,4) benzodiazepine-3-carboxylate. Flumazenil has an imidazobenzodiazepine structure, a calculated molecular weight of 303.3.
Flumazenil is a white to off-white crystalline compound with an octanol:buffer partition coefficient of 14 to 1 at pH 7.4. It is insoluble in water but slightly soluble in acidic aqueous solutions. MAZICON is available as a sterile parenteral dosage form for intravenous administration. Each mL contains 0.1 mg of flumazenil compounded with 1.8 mg of methylparaben, 0.2 mg of propylparaben, 0.9% sodium chloride, 0.01% edetate disodium, and 0.01% acetic acid; the pH is adjusted to approximately 4 with hydrochloric acid and/or, if necessary, sodium hydroxide.

CLINICAL PHARMACOLOGY: Flumazenil, an imidazobenzodiazepine derivative, antagonizes the actions of benzodiazepines on the central nervous system. Flumazenil competitively inhibits the activity at the benzodiazepine recognition site on the GABA/benzodiazepine receptor complex. Flumazenil is a weak partial agonist in some animal models of activity, but has little or no agonist activity in man.
Flumazenil does not antagonize the central nervous system effects of drugs affecting GABA-ergic neurons by means other than the benzodiazepine receptor (including ethanol, barbiturates, or general anesthetics) and does not reverse the effects of opioids.
PHARMACODYNAMICS: Intravenous MAZICON has been shown to antagonize sedation, impairment of recall and psychomotor impairment produced by benzodiazepines in healthy human volunteers.
The duration and degree of reversal of benzodiazepine effects are related to the dose and plasma concentrations of flumazenil as shown in the following data from a study in normal volunteers.

Magnitude and Duration of Reversal of Sedation as a Function of Flumazenil Dose*
Flumazenil doses of 0.2, 0.6 & 1.0 mg
(blood level in ng/mL)



*Sedation produced by midazolam infusion at a rate of 0.06 - 0.20 mg/kg/hr in healthy volunteers

Generally, doses of approximately 0.1 to 0.2 mg (corresponding to peak plasma levels of 3 to 6 ng/mL) produce partial antagonism, whereas higher doses of 0.4 to 1.0 mg (peak plasma levels of 12 to 28 ng/mL) usually produce complete antagonism in patients who have received the usual sedating doses of benzodiazepines. The onset of reversal is usually evident within 1 to 2 minutes after the injection is completed. Eighty percent response will be reached within 3 minutes, with the peak effect occurring at 6 to 10 minutes. The duration and degree of reversal are related to the plasma concentration of the sedating benzodiazepine as well as the dose of MAZICON given.
In healthy volunteers, MAZICON did not alter intraocular pressure when given alone and reversed the decrease in intraocular pressure seen after administration of midazolam.
PHARMACOKINETICS: After IV administration, plasma concentrations of flumazenil follow a two compartment open pharmacokinetic model with an initial distribution half-life of 7 to 15 minutes and a terminal half-life of 41 to 79 minutes. Peak concentrations of flumazenil are proportional to dose, with an apparent initial volume of distribution of 0.5 L/kg. After redistribution the apparent volume of distribution (V_{ss}) ranges from 0.77 to 1.60 L/kg. Protein binding is approximately 50% and the drug shows no preferential partitioning into red blood cells. Flumazenil is a highly extracted drug. Clearance of flumazenil occurs primarily by hepatic metabolism and is dependent on hepatic blood flow. In pharmacokinetic studies of normal volunteers, total clearance ranges from 0.7 to 1.3 L/hr/kg, with less than 1% of the administered dose eliminated unchanged in the urine. The major metabolites of flumazenil identified in urine are the de-ethylated free acid and its glucuronide conjugate. In preclinical studies there was no evidence of pharmacologic activity exhibited by the de-ethylated free acid. Elimination of radiolabelled drug is essentially complete within 72 hours, with 90% to 95% of the radioactivity appearing in urine and 5% to 10% in the feces.

Pharmacokinetic Parameters Following a 5-minute Infusion of a total of 1.0 mg of MAZICON Mean (Coefficient of variation, Range)

C_{max} (ng/mL)	24 (38%, 11-43)
AUC (ng•hr/mL)	15 (22%, 10-22)
V_{ss} (L/kg)	1 (24%, 0.8-1.6)
Cl (L/hr/kg)	1 (20%, 0.7-1.4)
Half-life (min)	54 (21%, 41-79)

The pharmacokinetics of flumazenil are not significantly affected by gender, age, renal failure (creatinine clearance <10 mL/min), or hemodialysis beginning 1 hour after drug administration. Mean total clearance is decreased to 40% to 60% of normal in patients with moderate liver dysfunction and to 25% of normal in patients with severe liver dysfunction compared with age-matched healthy subjects. This results in a prolongation of the half-life from 0.8 hours in healthy subjects to 1.3 hours in patients with moderate hepatic impairment and 2.4 hours in severely impaired patients. Ingestion of food during an intravenous infusion of the drug results in a 50% increase in clearance, most likely due to the increased hepatic blood flow that accompanies a meal. The pharmacokinetic profile of flumazenil is unaltered in the presence of benzodiazepine agonists and the kinetic profiles of those benzodiazepines are unaltered by flumazenil.

CLINICAL TRIALS: MAZICON has been administered to reverse the effects of benzodiazepines in conscious sedation, general anesthesia, and the management of suspected benzodiazepine overdose.
CONSCIOUS SEDATION: MAZICON was studied in four trials in 970 patients who received an average of 30 mg diazepam or 10 mg midazolam for sedation (with or without a narcotic) in conjunction with both inpatient and outpatient diagnostic or surgical procedures. MAZICON was effective in reversing the sedating and psychomotor effects of the benzodiazepine, however, amnesia was less completely and less consistently reversed. In these studies, MAZICON was administered as an initial dose of 0.4 mg I.V. (two doses of 0.2 mg) with additional 0.2 mg doses as needed to achieve complete awakening, up to a maximum total dose of 1.0 mg. Seventy-eight percent of patients receiving flumazenil responded by becoming completely alert. Of those patients, approximately half responded to doses of 0.4 to 0.6 mg, while the other half responded to doses of 0.8 to 1.0 mg. Adverse effects were infrequent in patients who received 1 mg of MAZICON or less, although injection site pain, agitation and anxiety did occur. Reversal of sedation was not associated with any increase in the frequency of inadequate analgesia or increase in narcotic demand in these studies. While most patients remained alert throughout the 3 hour post-procedure observation period, resedation was observed to occur in 3% to 9% of the patients, and was most common in patients who had received high doses of benzodiazepine. (See PRECAUTIONS.)
GENERAL ANESTHESIA: MAZICON was studied in four trials in 644 patients who received midazolam as an induction and/or maintenance agent in both balanced and inhalational anesthesia. Midazolam was generally administered in doses ranging from 5 to 80 mg, alone and/or in conjunction with muscle relaxants, nitrous oxide, regional or local anesthetics, narcotics and/or inhalational anesthetics. Flumazenil was given as an initial dose of 0.2 mg IV, with additional 0.2 mg doses as needed to reach a complete response, up to a maximum total dose of 1.0 mg. These doses were effective in reversing sedation and restoring psychomotor function, but did not completely restore memory as tested by picture recall. MAZICON was not as effective in the reversal of sedation in patients who had received multiple anesthetic agents in addition to benzodiazepines.
Eighty-one percent of patients sedated with midazolam responded to flumazenil by becoming completely alert or just slightly drowsy. Of those patients, 36% responded to doses of 0.4 to 0.6 mg, while 64% responded to doses of 0.8 to 1.0 mg.
Resedation in patients who responded to MAZICON occurred in 10% to 15% of patients studied and was more common with larger doses of midazolam (>20 mg), long procedures (>60 minutes) and use of neuromuscular blocking agents. (See PRECAUTIONS.)
MANAGEMENT OF SUSPECTED BENZODIAZEPINE OVERDOSE: MAZICON was studied in two trials in 497 patients who were presumed to have taken an overdose of a benzodiazepine, either alone or in combination with a variety of other agents. In these trials, 299 patients were proven to have taken a benzodiazepine as part of the overdose, and 80% of the 148 who received MAZICON responded by an improvement in level of consciousness. Of the patients who responded to flumazenil, 75% responded to a total dose of 1.0 to 3.0 mg. Reversal of sedation was associated with an increased frequency of symptoms of CNS excitation. Of the

patients treated with flumazenil, 1% to 3% were treated for agitation or anxiety. Serious side effects were uncommon, but six seizures were observed in 446 patients treated with flumazenil in these studies. Four of these 6 patients had ingested a large dose of cyclic antidepressants, which increased the risk of seizures. (See WARNINGS.)

INDIVIDUALIZATION OF DOSAGE: GENERAL PRINCIPLES: The serious adverse effects of MAZICON are related to the reversal of benzodiazepine effects. Using more than the minimally effective dose of MAZICON is tolerated by most patients but may complicate the management of patients who are physically dependent on benzodiazepines or patients who are depending on benzodiazepines for therapeutic effect (such as suppression of seizures in cyclic antidepressant overdose).
In high-risk patients, it is important to administer the smallest amount of MAZICON that is effective. The 1-minute wait between individual doses in the dose-titration recommended for general clinical populations may be too short for high risk patients. This is because it takes 6 to 10 minutes for any single dose of flumazenil to reach full effects. Practitioners should slow the rate of administration of MAZICON administered to high risk patients as recommended below.
ANESTHESIA AND CONSCIOUS SEDATION: MAZICON is well tolerated at the recommended doses in individuals who have no tolerance to (or dependence on) benzodiazepines. The recommended dosages and titration rates in anesthesia and conscious sedation (0.2 to 1.0 mg given at 0.2 mg/min) are well tolerated in patients receiving the drug for reversal of a single benzodiazepine exposure in most clinical settings (see Adverse Events). The major risk will be resedation because the duration of effect of a long-acting (or large dose of a short-acting) benzodiazepine may exceed that of MAZICON. Resedation may be treated by giving a repeat dose at no less than 20-minute intervals. For repeat treatment, no more than 1.0 mg (at 0.2 mg/min doses) should be given at any one time and no more than 3.0 mg should be given in any one hour.
OVERDOSE PATIENTS: The risk of confusion, agitation, emotional lability and perceptual distortion with the doses recommended in patients with benzodiazepine overdose (3 to 5 mg administered as 0.5 mg/min) may be greater than that expected with lower doses and slower administration. The recommended doses represent a compromise between a desirable slow awakening and the need for prompt response and a persistent effect in the overdose situation. If circumstances permit, the physician may elect to use the 0.2 mg/minute titration rate to slowly awaken the patient over 5 to 10 minutes, which may help to reduce signs and symptoms on emergence.
MAZICON has no effect in cases where benzodiazepines are not responsible for sedation. Once doses of 3 to 5 mg have been reached without clinical response, additional MAZICON is likely to have no effect.
PATIENTS TOLERANT TO BENZODIAZEPINES: MAZICON may cause benzodiazepine withdrawal symptoms in individuals who have been taking benzodiazepines long enough to have some degree of tolerance. Patients who had been taking benzodiazepines prior to entry into the MAZICON trials who were given flumazenil in doses over 1 mg experienced withdrawal-like events 2 to 5 times more frequently than patients who received less than 1 mg.
In patients who may have tolerance to benzodiazepines, as indicated by clinical history or by the need for larger than usual doses of benzodiazepine, slower titration rates of 0.1 mg/min and lower total doses may help reduce the frequency of emergent confusion and agitation. In such cases special care must be taken to monitor the patients for resedation because of the lower doses of MAZICON used.
PATIENTS PHYSICALLY DEPENDENT ON BENZODIAZEPINES: MAZICON is known to precipitate withdrawal seizures in patients who are physically dependent on benzodiazepines, even if such dependence was established in a relatively few days of high dose sedation in Intensive Care Unit environments. The risk of either seizures or resedation in such cases is high and patients have experienced seizures before regaining consciousness. MAZICON should be used in such settings with extreme caution, since the use of flumazenil in this situation has not been studied and no information as to dose and rate of titration is available. MAZICON should be used in such patients only if the potential benefits of using the drug outweigh the risks of precipitated seizures. Physicians are directed to the scientific literature for the most current information in this area.

INDICATIONS AND USAGE: MAZICON is indicated for the complete or partial reversal of the sedative effects of benzodiazepines in cases where general anesthesia has been induced and/or maintained with benzodiazepines, where sedation has been produced with benzodiazepines for diagnostic and therapeutic procedures, and for the management of benzodiazepine overdose.

CONTRAINDICATIONS: MAZICON is contraindicated:

- In patients with a known hypersensitivity to flumazenil or to benzodiazepines.
- In patients who have been given a benzodiazepine for control of a potentially life-threatening condition (*e.g.* control of intracranial pressure or status epilepticus).
- In patients who are showing signs of serious cyclic antidepressant overdose. (See WARNINGS.)

WARNINGS:

THE USE OF MAZICON HAS BEEN ASSOCIATED WITH THE OCCURRENCE OF SEIZURES.
THESE ARE MOST FREQUENT IN PATIENTS WHO HAVE BEEN ON BENZODIAZEPINES FOR LONG-TERM SEDATION OR IN OVERDOSE CASES WHERE PATIENTS ARE SHOWING SIGNS OF SERIOUS CYCLIC ANTIDEPRESSANT OVERDOSE.
PRACTITIONERS SHOULD INDIVIDUALIZE THE DOSAGE OF MAZICON AND BE PREPARED TO MANAGE SEIZURES.

Risk of Seizures: The reversal of benzodiazepine effects may be associated with the onset of seizures in certain high-risk populations. Possible risk factors for seizures include: concurrent major sedative-hypnotic drug withdrawal, recent therapy with repeated doses of parenteral benzodiazepines, myoclonic jerking or seizure activity prior to flumazenil administration in overdose cases, or concurrent cyclic antidepressant poisoning.
MAZICON is not recommended in cases of serious cyclic antidepressant poisoning, as manifested by motor abnormalities (twitching, rigidity, focal seizure), dysrhythmia (wide QRS, ventricular dysrhythmia, heart block), anticholinergic signs (mydriasis, dry mucosa, hypo-peristalsis), and cardiovascular collapse at presentation. In such cases MAZICON should be withheld and the patient should be allowed to remain sedated (with ventilatory and circulatory support as needed) until the signs of antidepressant toxicity have subsided. Treatment with MAZICON has no known benefit to the seriously ill mixed-overdose patient other than reversing sedation and should not be used in cases where seizures (from any cause) are likely.
Most convulsions associated with flumazenil administration require treatment and have been successfully managed with benzodiazepines, phenytoin or barbiturates. Because of the presence of flumazenil, higher than usual doses of benzodiazepines may be required.

HYPOVENTILATION: Patients who have received MAZICON for the reversal of benzodiazepine effects (after conscious sedation or general anesthesia) should be monitored for resedation, respiratory depression, or other residual benzodiazepine effects for an appropriate period (up to 120 minutes) based on the dose and duration of effect of the benzodiazepine employed.
This is because MAZICON has not been established as an effective treatment for hypoventilation due to benzodiazepine administration. The availability of flumazenil does not diminish the need for prompt detection of hypoventilation and the ability to effectively intervene by establishing an airway and assisting ventilation.
MAZICON may not fully reverse postoperative airway problems or ventilatory insufficiency induced by benzodiazepines. In addition, even if MAZICON is initially effective, such problems may recur because the effects of MAZICON wear off before the effects of many benzodiazepines.
Overdose cases should always be monitored for resedation until the patients are stable and resedation is unlikely.

PRECAUTIONS: RETURN OF SEDATION: MAZICON may be expected to improve the alertness of patients recovering from a procedure involving sedation or anesthesia with benzodiazepines, but should not be substituted for an adequate period of post-procedure monitoring. The availability of MAZICON does not reduce the risks associated with the use of large doses of benzodiazepines for sedation.
Patients should be monitored for resedation, respiratory depression (see WARNINGS), or other persistent or recurrent agonist effects for an adequate period of time after administration of MAZICON.
Resedation is least likely in cases where MAZICON is administered to reverse a low dose of a short-acting benzodiazepine (<10 mg midazolam). It is most likely in cases where a large single or cumulative dose of a benzodiazepine has been given in the course of a long procedure along with neuromuscular blocking agents and multiple anesthetic agents.
Profound resedation was observed in 1% to 3% of patients in the clinical studies. In clinical situations where resedation must be prevented, physicians may wish to repeat the initial dose (up to 1 mg of MAZICON given at 0.2 mg/min) at 30 minutes and possibly again at 60 minutes. This dosage schedule, although not studied in clinical trials, was effective in preventing resedation in a pharmacologic study in normal volunteers.
USE IN THE ICU: MAZICON should be used with caution in the Intensive Care Unit because of the increased risk of unrecognized benzodiazepine dependence in such settings. MAZICON may produce convulsions in patients physically dependant on benzodiazepines. (See INDIVIDUALIZATION OF DOSAGE AND WARNINGS.)
Administration of MAZICON to diagnose benzodiazepine-induced sedation in the Intensive Care Unit is not recommended due to the risk of adverse events as described above. In addition, the prognostic significance of a patient's failure to respond to flumazenil in cases confounded by metabolic disorder, traumatic injury, drugs other than benzodiazepines, or any other reasons not associated with benzodiazepine receptor occupancy is not known.

USE IN OVERDOSE: MAZICON is intended as an adjunct to, not as a substitute for, proper management of airway, assisted breathing, circulatory access and support, internal decontamination by lavage and charcoal, and adequate clinical evaluation.

Necessary measures should be instituted to secure airway, ventilation and intravenous access prior to administering flumazenil. Upon arousal patients may attempt to withdraw endotracheal tubes and/or intravenous lines as the result of confusion and agitation following awakening.

HEAD INJURY: MAZICON should be used with caution in patients with head injury as it may be capable of precipitating convulsions or altering cerebral blood flow in patients receiving benzodiazepines. It should be used only by practitioners prepared to manage such complications should they occur.

USE WITH NEUROMUSCULAR BLOCKING AGENTS: MAZICON should not be used until the effects of neuromuscular blockade have been fully reversed.

USE IN PSYCHIATRIC PATIENTS: MAZICON has been reported to provoke panic attacks in patients with a history of panic disorder.

PAIN ON INJECTION: To minimize the likelihood of pain or inflammation at the injection site, MAZICON should be administered through a freely flowing intravenous infusion into a large vein. Local irritation may occur following extravasation into perivascular tissues.

USE IN RESPIRATORY DISEASE: The primary treatment of patients with serious lung disease who experience serious respiratory depression due to benzodiazepines should be appropriate ventilatory support (See PRECAUTIONS) rather than the administration of MAZICON. Flumazenil is capable of partially reversing benzodiazepine-induced alterations in ventilatory drive in healthy volunteers, but has not been shown to be clinically effective.

USE IN CARDIOVASCULAR DISEASE: MAZICON did not increase the work of the heart when used to reverse benzodiazepines in cardiac patients when given at a rate of 0.1 mg/min in total doses of less than 0.5 mg in studies reported in the clinical literature. Flumazenil alone had no significant effects on cardiovascular parameters when administered to patients with stable ischemic heart disease.

USE IN LIVER DISEASE: The clearance of MAZICON is reduced to 40% to 60% of normal in patients with mild to moderate hepatic disease and to 25% of normal in patients with severe hepatic dysfunction. (See PHARMACOKINETICS.) While the dose of flumazenil used for initial reversal of benzodiazepine effects is not affected, repeat doses of the drug in liver disease should be reduced in size or frequency.

USE IN DRUG AND ALCOHOL DEPENDENT PATIENTS: MAZICON should be used with caution in patients with alcoholism and other drug dependencies due to the increased frequency of benzodiazepine tolerance and dependence observed in these patient populations.

MAZICON is not recommended either as a treatment for benzodiazepine dependence or for the management of protracted benzodiazepine abstinence syndromes, as such use has not been studied.

The administration of flumazenil can precipitate benzodiazepine withdrawal in animals and man. This has been seen in healthy volunteers treated with therapeutic doses of oral lorazepam for up to 2 weeks who exhibited effects such as hot flushes, agitation and tremor when treated with cumulative doses of up to 3 mg doses of flumazenil.

Similar adverse experiences suggestive of flumazenil precipitation of benzodiazepine withdrawal have occurred in some patients in clinical trials. Such patients had a short-lived syndrome characterized by dizziness, mild confusion, emotional lability, agitation (with signs and symptoms of anxiety), and mild sensory distortions. This response was dose-related, most common at doses above 1 mg, rarely required treatment other than reassurance and was usually short lived. When required (5 to 10 cases), these patients were successfully treated with usual doses of a barbiturate, a benzodiazepine, or other sedative drug.

Practitioners should assume that flumazenil administration may trigger dose-dependent withdrawal syndromes in patients with established physical dependence on benzodiazepines and may complicate the management of withdrawal syndromes for alcohol, barbiturates and cross-tolerant sedatives.

DRUG INTERACTIONS: Interaction with central nervous system depressants other than benzodiazepines has not been specifically studied; however, no deleterious interactions were seen when MAZICON was administered after narcotics, inhalational anesthetics, muscle relaxants and muscle relaxant antagonists administered in conjunction with sedation or anesthesia.

Particular caution is necessary when using MAZICON in cases of mixed drug overdosage since the toxic effects (such as convulsions and cardiac dysrhythmias) of other drugs taken in overdose (especially cyclic antidepressants) may emerge with the reversal of the benzodiazepine effect by flumazenil. (See WARNINGS.)

The pharmacokinetics of benzodiazepines are unaltered in the presence of flumazenil.

USE IN AMBULATORY PATIENTS: The effects of MAZICON may wear off before a long-acting benzodiazepine is completely cleared from the body. In general, if a patient shows no signs of sedation within 2 hours after a 1.0 mg dose of flumazenil, serious resedation at a later time is unlikely. An adequate period of observation must be provided for any patient in whom either long-acting benzodiazepines (such as diazepam) or large doses of short-acting benzodiazepines (such as >10 mg of midazolam) have been used. (See INDIVIDUALIZATION OF DOSAGE.)

Because of the increased risk of adverse reactions in patients who have been taking benzodiazepines on a regular basis, it is particularly important that physicians query carefully about benzodiazepine, alcohol and sedative use as part of the history prior to any procedure in which the use of MAZICON is planned. (See DRUG AND ALCOHOL DEPENDENT PATIENTS.)

INFORMATION FOR PATIENTS: MAZICON does not consistently reverse amnesia. Patients cannot be expected to remember information told to them in the post-procedure period and instructions given to patients should be reinforced in writing or given to a responsible family member. Physicians are advised to discuss with their patients, both before surgery and at discharge, that although the patient may feel alert at the time of discharge, the effects of the benzodiazepine may recur. As a result, the patient should be instructed, preferably in writing, that their memory and judgment may be impaired and specifically advised:

1. Not to engage in any activities requiring complete alertness, and not to operate hazardous machinery or a motor vehicle until at least 18 to 24 hours after discharge, and it is certain no residual sedative effects of the benzodiazepine remain.
2. Not to take any alcohol or non-prescription drugs for 18 to 24 hours after flumazenil administration or if the effects of the benzodiazepine persist.

LABORATORY TESTS: No specific laboratory tests are recommended to follow the patient's response or to identify possible adverse reactions.

DRUG/LABORATORY TEST INTERACTIONS: The possible interaction of flumazenil with commonly used laboratory tests has not been evaluated.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: No studies in animals to evaluate the carcinogenic potential of flumazenil have been conducted.

Mutagenesis: No evidence for mutagenicity was noted in the Ames test using five different tester strains. Assays for mutagenic potential in *S. cerevisiae* D7 and in Chinese hamster cells were considered to be negative as were blastogenesis assays *in vitro* in peripheral human lymphocytes and *in vivo* in a mouse micronucleus assay. Flumazenil caused a slight increase in unscheduled DNA synthesis in rat hepatocyte culture at concentrations which were also cytotoxic; no increase in DNA repair was observed in male mouse germ cells in an *in vivo* DNA repair assay.

Impairment of fertility: A reproduction study in male and female rats did not show any impairment of fertility at oral dosages of 125 mg/kg/day. From the available data on the area under the curve (AUC) in animals and man the dose represented 120 x the human exposure from a maximum recommended intravenous dose of 5 mg.

PREGNANCY: CATEGORY C. There are no adequate and well-controlled studies of the use of flumazenil in pregnant women. Flumazenil should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Teratogenic Effects: Flumazenil has been studied for teratogenicity in rats and rabbits following oral treatments of up to 150 mg/kg/day. The treatments during the major organogenesis were on days 6 to 15 of gestation in the rat and days 6 to 18 of gestation in the rabbit. No teratogenic effects were observed in rats or rabbits at 150 mg/kg; the dose, based on the available data on the area under the plasma concentration-time curve (AUC) represented 120 x to 600 x the human exposure from a maximum recommended intravenous dose of 5 mg in humans. In rabbits, embryocidal effects (as evidenced by increased pre-implantation and post-implantation losses) were observed at 50 mg/kg or 200 x the human exposure from a maximum recommended intravenous dose of 5 mg. The no-effect dose of 15 mg/kg in rabbits represents 60 x the human exposure.

Nonteratogenic Effects: An animal reproduction study was conducted in rats at oral dosages of 5, 25 and 125 mg/kg/day of flumazenil. Pup survival was decreased during the lactating period, pup liver weight at weaning was increased for the high-dose group (125 mg/kg/day) and incisor eruption and ear opening in the offspring were delayed; the delay in ear opening was associated with a delay in the appearance of the auditory startle response. No treatment-related adverse effects were noted for the other dose groups. Based on the available data from AUC, the effect level (125 mg/kg), represents 120 x the human exposure from 5 mg, the maximum recommended intravenous dose in humans. The no-effect level represents 24 x the human exposure from an intravenous dose of 5 mg.

LABOR AND DELIVERY: The use of MAZICON to reverse the effects of benzodiazepines used during labor and delivery is not recommended because the effects of the drug in the newborn are unknown.

NURSING MOTHERS: Caution should be exercised when deciding to administer MAZICON to a nursing woman because it is not known whether flumazenil is excreted in human milk.

PEDIATRIC USE: MAZICON is not recommended for use in children (either for the reversal of sedation, the management of overdose or the resuscitation of the newborn), as no clinical studies have been performed to determine the risks, benefits and dosages to be used.

GERIATRIC USE: The pharmacokinetics of flumazenil have been studied in the elderly and are not significantly different from younger patients. Several studies of MAZICON in patients over the age of 65 and one study in patients over the age of 80 suggest that while the doses of benzodiazepine used to induce sedation should be reduced, ordinary doses of MAZICON may be used for reversal.

ADVERSE REACTIONS: SERIOUS ADVERSE REACTIONS: Deaths have occurred in patients who received MAZICON in a variety of clinical settings. The majority of deaths occurred in patients with serious underlying disease or in patients who had ingested large amounts of non-benzodiazepine drugs, (usually cyclic antidepressants) as part of an overdose.

Serious adverse events have occurred in all clinical settings, and convulsions are the most common serious adverse event reported. MAZICON administration has been associated with the onset of convulsions in patients who are relying on benzodiazepine effects to control seizures, are physically dependent on benzodiazepines, or who have ingested large doses of other drugs. (See WARNINGS.)

Two of the 446 patients who received MAZICON in controlled clinical trials for the management of a benzodiazepine overdosage had cardiac dysrhythmias (1 ventricular tachycardia, 1 junctional tachycardia).

ADVERSE EVENTS IN CLINICAL STUDIES: The following adverse reactions were considered to be related to MAZICON administration (both alone and for the reversal of benzodiazepine effects) and were reported in studies involving 1875 individuals who received flumazenil in controlled trials. Adverse events most frequently associated with flumazenil alone were limited to dizziness, injection site pain, increased sweating, headache and abnormal or blurred vision (3% to 9%).

BODY AS A WHOLE: Fatigue (asthenia, malaise), Headache, Injection Site Pain*, Injection Site Reaction (thrombophlebitis, skin abnormality, rash)

CARDIOVASCULAR SYSTEM: Cutaneous vasodilation (sweating, flushing, hot flushes)

DIGESTIVE SYSTEM: Nausea and Vomiting (11%)

NERVOUS SYSTEM: Agitation (anxiety, nervousness, dry mouth, tremor, palpitations, insomnia, dyspnea, hyperventilation)*, Dizziness (vertigo, ataxia) (10%), Emotional lability (crying abnormal, depersonalization, euphoria, increased tears, depression, dysphoria, paranoia).

SPECIAL SENSES: Abnormal Vision (visual field defect, diplopia), Paresthesia (sensation abnormal, hypoesthesia)

All adverse reactions occurred in 1% to 3% of cases unless otherwise marked.

*indicates reaction in 3% to 9% of cases.

Observed percentage reported if greater than 9%.

The following adverse events were observed infrequently (less than 1%) in the clinical studies, but were judged as probably related to MAZICON administration and/or reversal of benzodiazepine effects:

NERVOUS SYSTEM: Confusion (difficulty concentrating, delirium), Convulsions (see WARNINGS), Somnolence (stupor).

SPECIAL SENSES: Abnormal Hearing (transient hearing impairment, hyperacusis, tinnitus).

The following adverse events occurred with frequencies less than 1% in the clinical trials. Their relationship to MAZICON administration is unknown, but they are included as alerting information for the physician.

BODY AS A WHOLE: Rigors, shivering.

CARDIOVASCULAR: Arrhythmia (atrial, nodal, ventricular extrasystoles), bradycardia, tachycardia, hypertension, chest pain.

DIGESTIVE SYSTEM: Hiccup.

NERVOUS SYSTEM: Speech disorder (dysphonia, thick tongue).

Not included in this list is operative site pain that occurred with the same frequency in patients receiving placebo as in patients receiving flumazenil for reversal of sedation following a surgical procedure.

DRUG ABUSE AND DEPENDENCE: MAZICON acts as a benzodiazepine antagonist, blocks the effects of benzodiazepines in animals and man, antagonizes benzodiazepine reinforcement in animal models, produces dysphoria in normal subjects, and has had no reported abuse in foreign marketing.

Although MAZICON has a benzodiazepine-like structure it does not act as a benzodiazepine agonist in man and is not a controlled substance.

OVERDOSAGE: Large intravenous doses of MAZICON, when administered to healthy normal volunteers in the absence of a benzodiazepine agonist, produced no serious adverse reactions, severe signs or symptoms, or clinically significant laboratory test abnormalities. In clinical studies, most adverse reactions to flumazenil were an extension of the pharmacologic effects of the drug in reversing benzodiazepine effects.

Reversal with an excessively high dose of MAZICON may produce anxiety, agitation, increased muscle tone, hyperesthesia and possibly convulsions. Convulsions have been treated with barbiturates, benzodiazepines and phenytoin, generally with prompt resolution of the seizures. (See WARNINGS.)

DOSE AND ADMINISTRATION: MAZICON is recommended for intravenous use only. It is compatible with 5% dextrose in water, lactated Ringer's and normal saline solutions. If MAZICON is drawn into a syringe or mixed with any of these solutions, it should be discarded after 24 hours. For optimum sterility, MAZICON should remain in the vial until just before use. As with all parenteral drug products, MAZICON should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

To minimize the likelihood of pain at the injection site, MAZICON should be administered through a freely running intravenous infusion into a large vein.

REVERSAL OF CONSCIOUS SEDATION OR IN GENERAL ANESTHESIA: For the reversal of the sedative effects of benzodiazepines administered for conscious sedation or general anesthesia, the recommended initial dose of MAZICON is 0.2 mg (2 mL) administered intravenously over 15 seconds. If the desired level of consciousness is not obtained after waiting an additional 45 seconds, a further dose of 0.2 mg (2 mL) can be injected and repeated at 60-second intervals where necessary (up to a maximum of 4 additional times) to a maximum total dose of 1 mg (10 mL). The dose should be individualized based on the patient's response, with most patients responding to doses of 0.6 to 1 mg. (See INDIVIDUALIZATION OF DOSAGE.)

In the event of resedation, repeated doses may be administered at 20 minute intervals as needed. For repeat treatment, no more than 1 mg (given as 0.2 mg/min) should be administered at any one time, and no more than 3 mg should be given in any one hour.

It is recommended that MAZICON be administered as the series of small injections described (not as a single bolus injection) to allow the practitioner to control the reversal of sedation to the approximate endpoint desired and to minimize the possibility of adverse effects. (See INDIVIDUALIZATION OF DOSAGE.)

MANAGEMENT OF SUSPECTED BENZODIAZEPINE OVERDOSE: For initial management of a known or suspected benzodiazepine overdose, the recommended initial dose of MAZICON is 0.2 mg (2 mL) administered intravenously over 30 seconds. If the desired level of consciousness is not obtained after waiting 30 seconds, a further dose of 0.3 mg (3 mL) can be administered over another 30 seconds. Further doses of 0.5 mg (5 mL) can be administered over 30 seconds at 1-minute intervals up to a cumulative dose of 3 mg.

Do not rush the administration of MAZICON. Patients should have a secure airway and intravenous access before administration of the drug and be awakened gradually. (See PRECAUTIONS.)

Most patients with benzodiazepine overdose will respond to a cumulative dose of 1-3 mg of MAZICON, and doses beyond 3 mg do not reliably produce additional effects. On rare occasions, patients with a partial response at 3 mg may require additional titration up to a total dose of 5 mg (administered slowly in the same manner).

If a patient has not responded 5 minutes after receiving a cumulative dose of 5 mg MAZICON, the major cause of sedation is likely not to be due to benzodiazepines, and additional MAZICON is likely to have no effect.

In the event of resedation, repeated doses may be given at 20-minute intervals if needed. For repeat treatment, no more than 1 mg (given as 0.5 mg/min) should be given at any one time and no more than 3 mg should be given in any one hour.

SAFETY AND HANDLING: MAZICON is supplied in sealed dosage forms and poses no known risk to the health care provider. Routine care should be taken to avoid aerosol generation when preparing syringes for injection, and spilled medication should be rinsed from the skin with cool water.

HOW SUPPLIED: 5 mL multiple-use vials containing 0.1 mg/mL flumazenil:
Boxes of 10 (NDC 0004-6904-14).
10 mL multiple-use vials containing 0.1 mg/mL flumazenil:
Boxes of 10 (NDC 0004-6905-14).
Store at 59° to 86° F (15° to 30° C).

Be Prepared for Malignant Hyperthermia

Fatalities resulting from malignant hyperthermia are **unexpected, unfair** and almost always, **unnecessary.**

Unexpected because the patient - child or adult - shows no outward signs of this genetic disorder. And there is no simple diagnostic test. Most people have never heard of malignant hyperthermia **until** it strikes.

Unfair because it is triggered by the patient's reaction to certain common anesthetics used during surgery. The life-threatening episode that results has nothing whatsoever to do with the condition requiring the surgery.

Unnecessary, in most cases, because preparedneess and prompt treatment can arrest the episode before it reaches dangerous levels. Persons who know of their susceptibility can have surgery safely using non-triggering anesthetics. When MH strikes unexpectedly during an operation, it can be brought under control by early diagnosis and immediate treatment.

As a medical professional, you can combat this silent killer. For the latest information on diagnosing and treating malignant hyperthermia, contact the Malignant Hyperthermia Association of the United States (MHAUS) at (203) 655-3007. It may mean the difference between life or death.

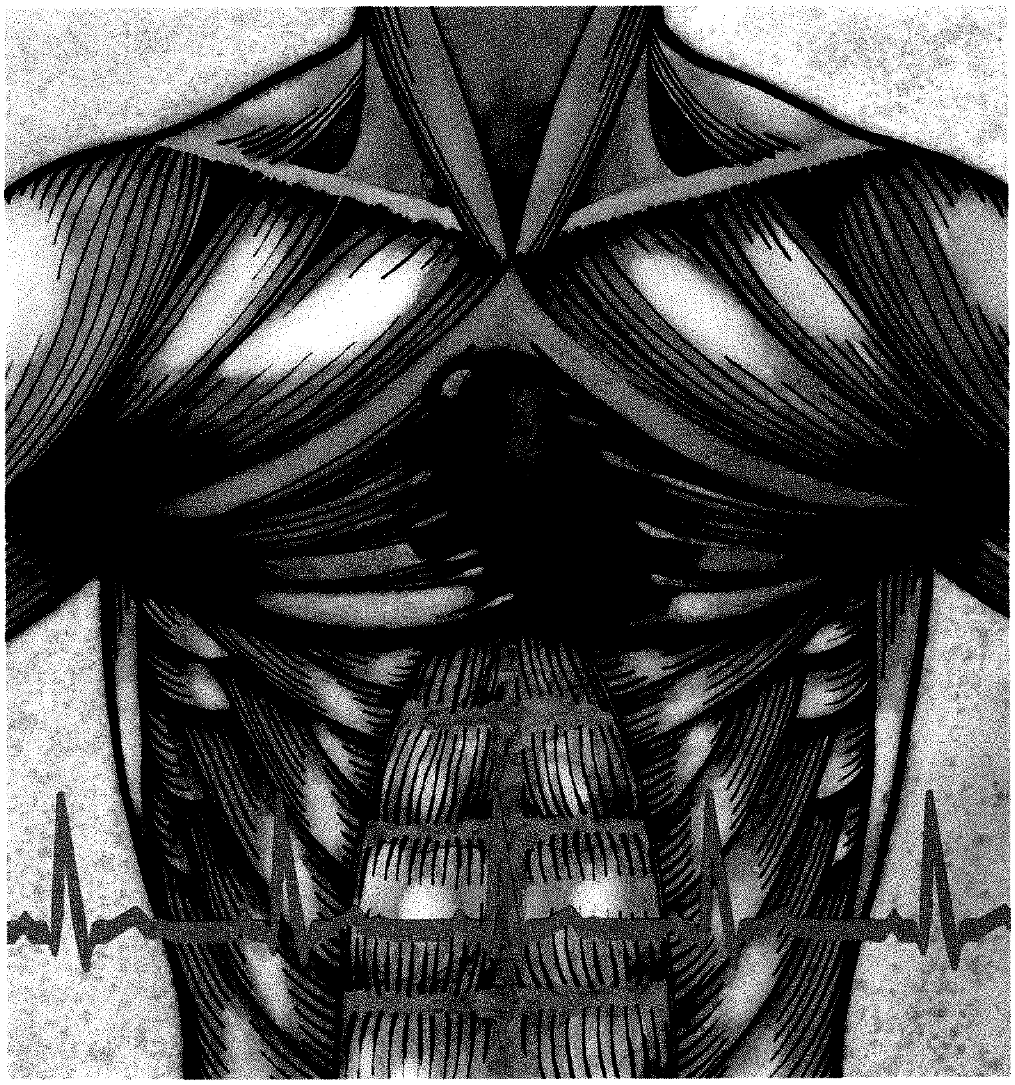
A Long-Acting Neuromuscular Blocker

Excellent
CV Stability



NUROMAX® INJECTION
(doxacurium chloride) 1 mg/mL

Please see brief summary of full prescribing information.

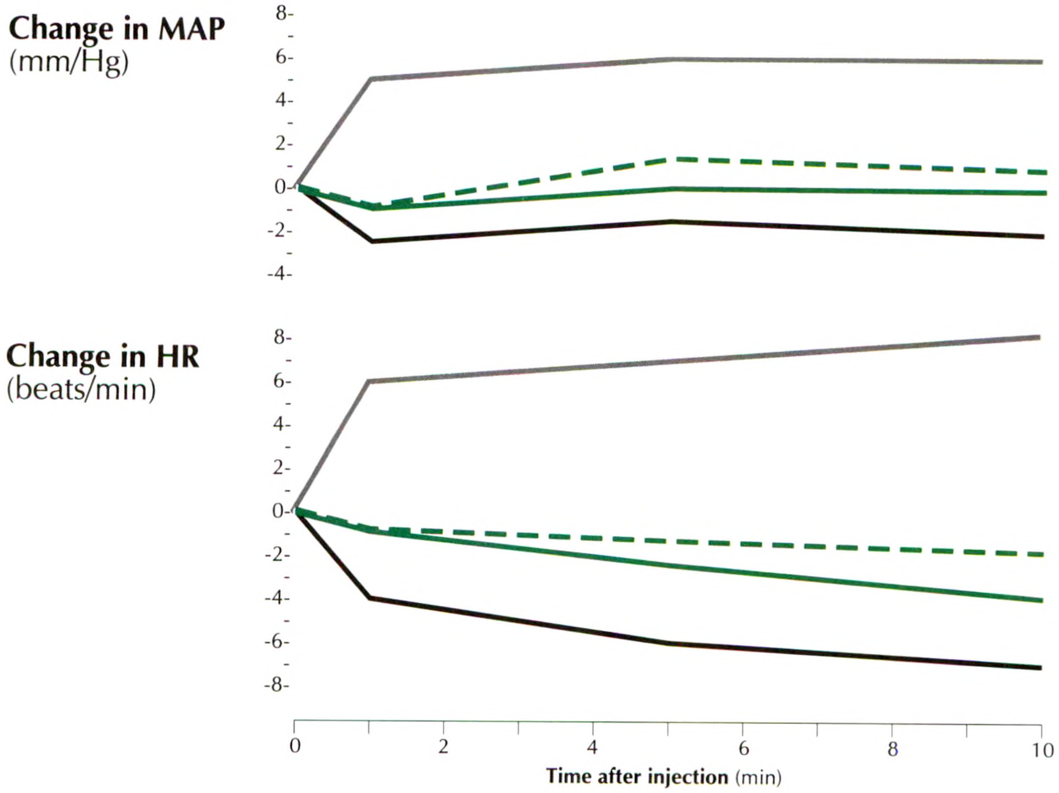
A Long-Acting Neuromuscular Blocker

NUROMAX® INJECTION

(doxacurium chloride)

Excellent CV Stability

Cardiovascular stability comparable with vecuronium

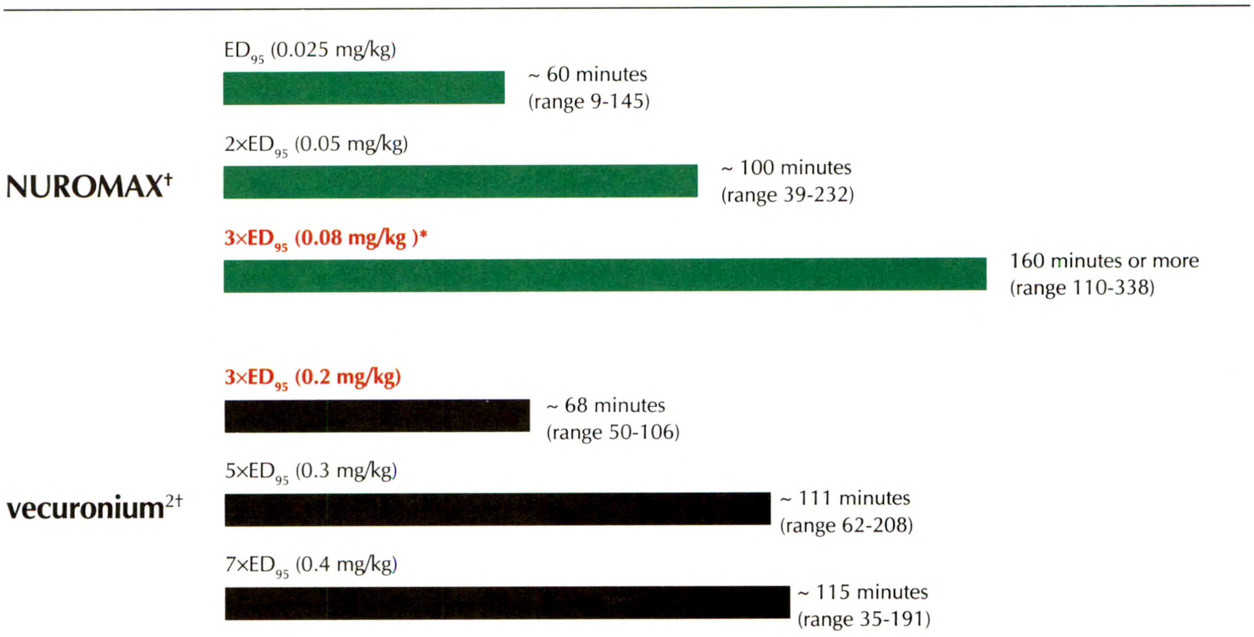


Emmott et al[1] compared the hemodynamic effects of Nuromax 0.037 and 0.075 mg/kg with the effects of pancuronium 0.09 mg/kg and vecuronium 0.075 mg/kg in 36 CABG patients (9 patients, each group).
Mean changes from baseline values of mean systemic arterial pressure (MAP) and heart rate (HR) at 1, 5 and 10 min after administration.
All routine cardiac and vasoactive medications were continued up to the morning of surgery.

▬ ▬ doxacurium 0.037 mg/kg	▬ pancuronium 0.09 mg/kg
▬ doxacurium 0.075 mg/kg	▬ vecuronium 0.075 mg/kg

Longer acting than "high-dose" vecuronium

Clinically effective block (time to 25% recovery)

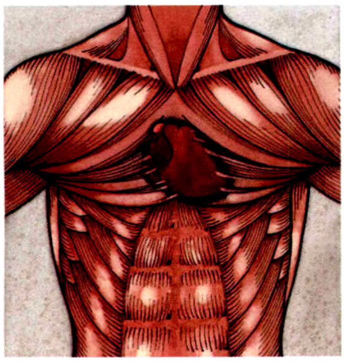


---

*This dose should be reserved for instances in which a need for very prolonged neuromuscular block is anticipated.

†Numbers shown are not directly comparable since these data have been compiled from different study populations.

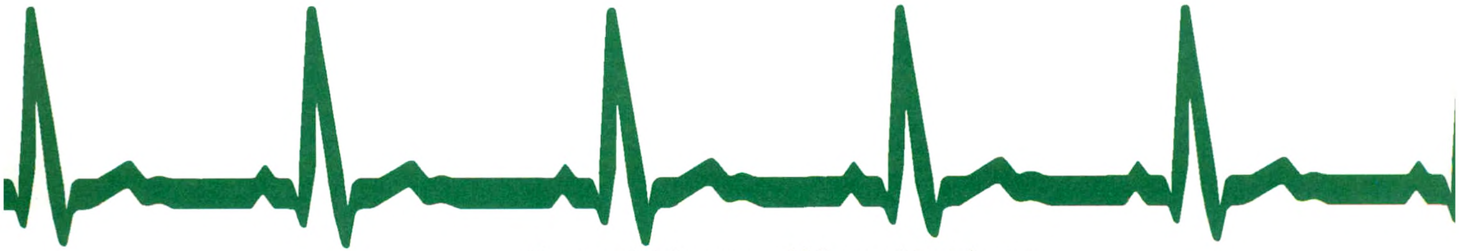
- **Cardiovascular stability comparable with normal saline** [3]
- **Noncumulative**
- **Ready-to-use solution**
- **Vials stored at room temperature, no refrigeration required**
- **Supplied as a 5 mL vial, 1 mg/mL**



NUROMAX® INJECTION

(doxacurium chloride) 1 mg/mL

Excellent for Long CV Procedures



Please see brief summary of full prescribing information

NUROMAX® INJECTION
(DOXACURIUM CHLORIDE)

Brief Summary

This drug should be administered only by adequately trained individuals familiar with its actions, characteristics, and hazards.

Individualization of Dosages: In elderly patients or patients who have impaired renal function, the potential for a prolongation of block may be reduced by decreasing the initial Nuromax dose and by titrating the dose to achieve the desired depth of block. In obese patients (patients weighing $\geq$ 30% more than ideal body weight for height), the Nuromax dose should be determined using the patient's ideal body weight (IBW), according to the following formulae:

Men: IBW in kg = [106 + (6 x inches in height above 5 feet)]/2.2
Women: IBW in kg = [100 + (5 x inches in height above 5 feet)]/2.2

Dosage requirements for patients with severe liver disease are variable; some patients may require a higher than normal initial Nuromax dose to achieve clinically effective block. Once adequate block is established, the clinical duration of block may be prolonged in such patients relative to patients with normal liver function.

As with pancuronium, metocurine, and vecuronium, resistance to Nuromax, manifested by a reduced intensity and/or shortened duration of block, must be considered when Nuromax is selected for use in patients receiving phenytoin or carbamazepine (see **Drug Interactions** subsection of PRECAUTIONS).

As with other nondepolarizing neuromuscular blocking agents, a reduction in dosage of Nuromax must be considered in cachectic or debilitated patients, in patients with neuromuscular diseases, severe electrolyte abnormalities, or carcinomatosis, and in other patients in whom potentiation of neuromuscular block or difficulty with reversal is anticipated. Increased doses of Nuromax may be required in burn patients (see PRECAUTIONS).

INDICATIONS AND USAGE: Nuromax is a long-acting neuromuscular blocking agent, indicated as an adjunct to general anesthesia, to provide skeletal muscle relaxation during surgery. Nuromax can also be used to provide skeletal muscle relaxation for endotracheal intubation.

CONTRAINDICATIONS: Nuromax is contraindicated in patients known to have hypersensitivity to it.

WARNINGS: NUROMAX SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH THE DRUG'S ACTIONS AND THE POSSIBLE COMPLICATIONS OF ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND AN ANTAGONIST ARE WITHIN IMMEDIATE REACH. IT IS RECOMMENDED THAT CLINICIANS ADMINISTERING LONG-ACTING NEUROMUSCULAR BLOCKING AGENTS SUCH AS NUROMAX EMPLOY A PERIPHERAL NERVE STIMULATOR TO MONITOR DRUG RESPONSE, NEED FOR ADDITIONAL RELAXANTS, AND ADEQUACY OF SPONTANEOUS RECOVERY OR ANTAGONISM.

NUROMAX HAS NO KNOWN EFFECT ON CONSCIOUSNESS, PAIN THRESHOLD, OR CEREBRATION. TO AVOID DISTRESS TO THE PATIENT, NEUROMUSCULAR BLOCK SHOULD NOT BE INDUCED BEFORE UNCONSCIOUSNESS.

Nuromax Injection is acidic (pH 3.9 to 5.0) and may not be compatible with alkaline solutions having a pH greater than 8.5 (*e.g.*, barbiturate solutions).

Nuromax Injection contains benzyl alcohol. In newborn infants, benzyl alcohol has been associated with an increased incidence of neurological and other complications which are sometimes fatal. See **Pediatric Use** subsection of PRECAUTIONS.

PRECAUTIONS: General: Nuromax has no clinically significant effects on heart rate; therefore, Nuromax will not counteract the bradycardia produced by many anesthetic agents or by vagal stimulation. Neuromuscular blocking agents may have a profound effect in patients with neuromuscular diseases (*e.g.*, myasthenia gravis and the myasthenic syndrome). In these and other conditions in which prolonged neuromuscular block is a possibility (*e.g.*, carcinomatosis), the use of a peripheral nerve stimulator and a small test dose of Nuromax is recommended to assess the level of neuromuscular block and to monitor dosage requirements. Shorter acting muscle relaxants than Nuromax may be more suitable for these patients.

Resistance to nondepolarizing neuromuscular blocking agents may develop in patients with burns depending upon the time elapsed since the injury and the size of the burn. Nuromax has not been studied in patients with burns. Acid-base and/or serum electrolyte abnormalities may potentiate or antagonize the action of neuromuscular blocking agents. The action of neuromuscular blocking agents may be enhanced by magnesium salts administered for the management of toxemia of pregnancy. Nuromax has not been studied in patients with asthma. No data are available to support the use of Nuromax by intramuscular injection. **Renal and Hepatic Disease:** Nuromax has been studied in patients with end-stage kidney (n=8) or liver (n=7) disease undergoing transplantation procedures (see CLINICAL PHARMACOLOGY). The possibility of prolonged neuromuscular block in patients undergoing renal transplantation and the possibility of a variable onset and duration of neuromuscular block in patients undergoing liver transplantation must be considered when Nuromax is used in such patients. **Obesity:** Administration of Nuromax on the basis of actual body weight is associated with a prolonged duration of action in obese patients (patients weighing $\geq$ 30% more than ideal body weight for height) (see CLINICAL PHARMACOLOGY). Therefore, the dose of Nuromax should be based upon ideal body weight in obese patients (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY). **Malignant Hyperthermia (MH):** In a study of MH-susceptible pigs, Nuromax did not trigger MH. Nuromax has not been studied in MH-susceptible patients. Since MH can develop in the absence of established triggering agents, the clinician should be prepared to recognize and treat MH in any patient scheduled for general anesthesia. **Long-Term Use in the Intensive Care Unit (ICU):** No data are available on the long-term use of Nuromax in patients undergoing mechanical ventilation in the ICU. **Drug Interactions:** Prior administration of succinylcholine has no clinically important effect on the neuromuscular blocking action of Nuromax. The use of Nuromax before succinylcholine to attenuate some of the side effects of succinylcholine has not been studied. There are no clinical data on concomitant use of Nuromax and other nondepolarizing neuromuscular blocking agents. Isoflurane, enflurane and halothane decrease the ED_{50} of Nuromax by 30% to 45%. These agents may also prolong the clinically effective duration of action by up to 25%. Other drugs which may enhance the neuromuscular blocking action of nondepolarizing agents such as Nuromax include certain antibiotics (*e.g.*, aminoglycosides, tetracyclines, bacitracin, polymyxins, lincomycin, clindamycin, colistin, and sodium colistimethate), magnesium salts, lithium, local anesthetics, procainamide, and quinidine. As with some other nondepolarizing neuromuscular blocking agents, the time of onset of neuromuscular block induced by Nuromax is lengthened and the duration of block is shortened in patients receiving phenytoin or carbamazepine. **Carcinogenesis, Mutagenesis, Impairment of Fertility:** Carcinogenesis and fertility studies have not been performed. Nuromax was evaluated in a battery of four short-term mutagenicity tests. It was non-mutagenic in the Ames Salmonella assay, in the mouse lymphoma assay, and in the human lymphocyte assay. In the *in vivo* rat bone marrow cytogenetic assay, statistically significant increases in the incidence of structural abnormalities, relative to vehicle controls, were observed in male rats dosed with 0.1 mg/kg (0.625 mg/m^2) Nuromax and sacrificed at 6 hours, but not at 24 or 48 hours, and in female rats dosed with 0.2 mg/kg (1.25 mg/m^2) Nuromax and sacrificed at 24 hours, but not at 6 or 48 hours. There was no increase in structural abnormalities in either male or female rats given 0.3 mg/kg (1.875 mg/m^2) Nuromax and sacrificed at 6, 24, or 48 hours. Thus, the incidence of abnormalities in the *in vivo* rat bone marrow cytogenetic assay was not dose-dependent and, therefore, the likelihood that the observed abnormalities were treatment-related or clinically significant is low. **Pregnancy:** Teratogenic Effects: Pregnancy Category C. Teratology testing in nonventilated, pregnant rats and mice treated subcutaneously with maximum subparalyzing doses of Nuromax revealed no maternal or fetal toxicity or teratogenic effects. There are no adequate and well-controlled studies of Nuromax in pregnant women. Because animal studies are not always predictive of human response and the doses used were subparalyzing, Nuromax should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Labor and Delivery:** The use of Nuromax during labor, vaginal delivery, or cesarean section has not been studied. It is not known whether Nuromax administered to the mother has immediate or delayed effects on the fetus. The duration of action of Nuromax exceeds the usual duration of operative obstetrics (cesarean section). Therefore, Nuromax is not recommended for use in patients undergoing C-section. **Nursing Mothers:** It is not known whether Nuromax is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised following Nuromax administration to a nursing woman. **Pediatric Use:** Nuromax has not been studied in children below the age of 2 years. See CLINICAL PHARMACOLOGY and DOSAGE AND ADMINISTRATION for clinical experience and recommendations for use in children 2 to 12 years of age. **Geriatric Use:** Nuromax has been used in elderly patients, including patients with significant cardiovascular disease. In elderly patients the onset of maximum block is slower and the duration of neuromuscular block produced by Nuromax is more variable and, in some cases, longer than in young adult patients (see **Pharmacodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY).

ADVERSE REACTIONS: The most frequent adverse effect of nondepolarizing blocking agents as a class consists of an extension of the pharmacological action beyond the time needed for surgery and anesthesia. This effect may vary from skeletal muscle weakness to profound and prolonged skeletal muscle paralysis resulting in respiratory insufficiency and apnea which require manual or mechanical ventilation until recovery is judged to be clinically adequate (see OVERDOSAGE). Inadequate reversal of neuromuscular block from Nuromax is possible, as with all nondepolarizing agents. Prolonged neuromuscular block and inadequate reversal may lead to postoperative complications. **Observed in Clinical Trials:** Adverse experiences were uncommon among the 1034 surgical patients and volunteers who received Nuromax and other drugs in U.S. clinical studies in the course of a wide variety of procedures conducted during balanced or inhalational anesthesia. The following adverse experiences were reported in patients administered Nuromax (all events judged by investigators during the clinical trials to have a possible causal relationship):

Incidence Greater than 1% - None

Incidence Less than 1% -

Cardiovascular*:	hypotension,† flushing,† ventricular fibrillation, myocardial infarction
Respiratory:	bronchospasm, wheezing
Dermatological:	urticaria, injection site reaction
Special Senses:	diplopia
Nonspecific:	difficult neuromuscular block reversal, prolonged drug effect, fever

* Reports of ventricular fibrillation (n=1) and myocardial infarction (n=1) were limited to ASA Class 3-4 patients undergoing cardiac surgery (n=142).

† 0.3% incidence. All other reactions unmarked were $\leq$ 0.1%.

OVERDOSAGE: Overdosage with neuromuscular blocking agents may result in neuromuscular block beyond the time needed for surgery and anesthesia. The primary treatment is maintenance of a patent airway and controlled ventilation until recovery of normal neuromuscular function is assured. Once evidence of recovery from neuromuscular block is observed, further recovery may be facilitated by administration of an anticholinesterase agent (*e.g.*, neostigmine, edrophonium) in conjunction with an appropriate anticholinergic agent (see **Antagonism of Neuromuscular Block**).

Antagonism of Neuromuscular Block: ANTAGONISTS (SUCH AS NEOSTIGMINE) SHOULD NOT BE ADMINISTERED PRIOR TO THE DEMONSTRATION OF SOME SPONTANEOUS RECOVERY FROM NEUROMUSCULAR BLOCK. THE USE OF A NERVE STIMULATOR TO DOCUMENT RECOVERY AND ANTAGONISM OF NEUROMUSCULAR BLOCK IS RECOMMENDED. T_4/T_1 SHOULD BE > ZERO BEFORE ANTAGONISM IS ATTEMPTED.

In an analysis of patients in whom antagonism of neuromuscular block was evaluated following administration of single doses of neostigmine averaging 0.06 mg/kg (range: 0.05 to 0.075) administered at approximately 25% T_1 spontaneous recovery during balanced anesthesia, 71% of patients exhibited $T_4/T_1 \geq 0.7$ before monitoring was discontinued. For these patients, the mean time to $T_4/T_1 \geq 0.7$ was 19 minutes (range: 7 to 55). As with other long-acting nondepolarizing neuromuscular blocking agents, the time for recovery of neuromuscular function following administration of neostigmine is dependent upon the level of residual neuromuscular block at the time of attempted reversal; longer recovery times than those cited above may be anticipated when neostigmine is administered at more profound levels of block (*i.e.*, at < 25% T_1 recovery).

Patients should be evaluated for adequate clinical evidence of antagonism, *e.g.*, 5-second head lift, and grip strength. Ventilation must be supported until no longer required. As with other neuromuscular blocking agents, physicians should be alert to the possibility that the action of the drugs used to antagonize neuromuscular block may wear off before the effects of Nuromax on the neuromuscular junction have declined sufficiently.

Antagonism may be delayed in the presence of debilitation, carcinomatosis, and the concomitant use of certain broad spectrum antibiotics, or anesthetic agents and other drugs which enhance neuromuscular block or separately cause respiratory depression (see **Drug Interactions** subsection of PRECAUTIONS). Under such circumstances the management is the same as that of prolonged neuromuscular block.

In clinical trials, a dose of 1 mg/kg edrophonium was not as effective as a dose of 0.06 mg/kg neostigmine in antagonizing moderate to deep levels of neuromuscular block (i.e., < 60% T_1 recovery). Therefore, the use of 1 mg/kg edrophonium is not recommended for reversal from moderate to deep levels of block. The use of pyridostigmine has not been studied.

Adults: *Initial Doses:* When administered as a component of a thiopental/narcotic induction-intubation paradigm as well as for production of long-duration neuromuscular block during surgery, 0.05 mg/kg (2 x ED_{95}) Nuromax produces good-to-excellent conditions for tracheal intubation in 5 minutes in approximately 90% of patients. Lower doses of Nuromax may result in a longer time for development of satisfactory intubation conditions. Clinically effective neuromuscular block may be expected to last approximately 100 minutes on average (range: 39 to 232) following 0.05 mg/kg Nuromax administered to patients receiving balanced anesthesia.

An initial Nuromax dose of 0.08 mg/kg (3 x ED_{95}) should be reserved for instances in which a need for very prolonged neuromuscular block is anticipated. In approximately 90% of patients, good-to-excellent intubation conditions may be expected in 4 minutes after this dose; however, clinically effective block may be expected to persist for as long as 160 minutes or more (range: 110 to 338) (see CLINICAL PHARMACOLOGY).

STORAGE: Store Nuromax Injection at room temperature of 15° to 25°C (59° to 77°F). DO NOT FREEZE.

Pulmonary Function and Stress Response After Laparoscopic Cholecystectomy: Comparison With Subcostal Incision and Influence of Thoracic Epidural Analgesia

Bart M. Rademaker, MD, Jan Ringers, MD, Joseph A. Odoom, MD, PhD,
Laurens T. de Wit, MD, Cor J. Kalkman, MD, PhD, and Johannes Oosting, PhD

Departments of Anesthesiology, Surgery, and Medical Physics, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands

Laparoscopic cholecystectomy (LPC) is increasingly used to treat symptomatic cholelithiasis. We compared the effects of cholecystectomy by subcostal incision to those of LPC on lung function and endocrine metabolic response. The effects of thoracic epidural analgesia for LPC were studied as well. Thirty patients undergoing elective cholecystectomy under general anesthesia were allocated to three study groups: group I, cholecystectomy by subcostal incision; group II, LPC; group III, LPC and epidural analgesia with 0.5% bupivacaine with epinephrine, followed by continuous epidural infusion of 6 mL of 0.5% bupivacaine. Forced vital capacity (FVC), peak expiratory flow, and forced expiratory volume in 1 s were measured with the patients in a half-sitting position. In all groups, sustained decreases in FVC, forced expiratory volume in 1 s, and peak expiratory flow were observed up to 24 h after surgery. Reduction of FVC was significantly more in group I compared with groups II and III ($P < 0.05$). The FVC in group I decreased from 3.8 ± 0.42 (SD) to 1.1 ± 0.27 L ($P < 0.01$), in group II from 3.6 ± 1.46 to 2.1 ± 0.94 L ($P < 0.05$), and in group III from 3.8 ± 0.92 to 2.8 ± 0.90 L ($P < 0.05$). In all groups, plasma glucose and cortisol increased after surgery compared with baseline levels ($P < 0.05$). At 240 min after surgery, a small but significant decrease of cortisol was measured in group III ($P < 0.05$). Patients in groups I and II received significantly more fentanyl during surgery and nicomorphine postoperatively compared with patients in group III ($P < 0.05$). In group III, epidural analgesia decreased visual analogue pain scores ($P < 0.05$), but there was no difference in pain scores between groups I and II. In conclusion, the endocrine metabolic response is not abolished after LPC. Thoracic epidural analgesia decreased postoperative pain and possibly attenuated the metabolic endocrine response, but it did not improve lung function after LPC. Nevertheless, pulmonary function is significantly better after LPC than after cholecystectomy via subcostal incision.

(Anesth Analg 1992;75:381–5)

Upper abdominal surgery is associated with postoperative pulmonary dysfunction in up to 48% of patients (1). Impaired diaphragmatic function, type of skin incision, postoperative pain, muscle paralysis, and decreased functional residual capacity have all been found to contribute to postoperative pulmonary dysfunction (2–4). Laparoscopic cholecystectomy (LPC) is a new surgical technique that is rapidly becoming the first choice for management of symptomatic cholelithiasis. The purpose of this study was to compare the effects of LPC with those of cholecystectomy by subcostal incision (CSI) on postoperative pulmonary function.

Because it has been postulated that decreasing or abolishing the metabolic endocrine response to surgery may reduce postoperative morbidity (5,6), we also studied the effects of LPC on the metabolic endocrine response to surgery.

Thoracic epidural analgesia combined with general anesthesia was used to evaluate the influence of pain after LPC on postoperative lung function and metabolic endocrine response.

Methods

The protocol of this study was institutionally approved. Thirty patients (ASA physical status I or II) undergoing elective cholecystectomy under general anesthesia gave informed consent to participate in the study. Patients were assigned to group I and underwent CSI whenever the instrumentation for

laparoscopic surgery was not available. Patients who underwent a laparoscopic procedure were assigned on an alternating basis to either group II or III. Patients in group II underwent LPC, as described by Dubois et al. (7) and patients in group III LPC under general anesthesia combined with epidural analgesia.

Diazepam (10 mg) was administered orally 1 h before induction of anesthesia. Standard monitoring was used. A radial artery was cannulated percutaneously with a 20-gauge cannula for arterial blood pressure measurement and blood sampling. The infusion regimen consisted of normal saline solution at a rate of 6 $mL \cdot kg^{-1} \cdot h^{-1}$ during the operation and for 4 h thereafter. In group III, a 16-gauge epidural catheter was inserted under local analgesia (5 mL of 1% lidocaine with 5 µg/mL of epinephrine) at T6-8 immediately before the induction of general anesthesia. After insertion of the epidural catheter, 10 mL of 0.5% bupivacaine with 5 µg/mL of epinephrine was injected, and the level of analgesia was confirmed with the pinprick method. In all groups, anesthesia was induced with thiopental (3–5 mg/kg), followed by vecuronium (0.1 mg/kg IV) to facilitate tracheal intubation. Anesthesia was maintained with 1.4% enflurane (inspired concentration) delivered through a Dräger vaporizer and oxygen in air (FIO_2 = 0.5). Ventilation was adjusted to maintain end-tidal CO_2 between 35 and 40 mm Hg. Additional doses of vecuronium were administered to maintain one or two responses to train-of-four stimulation. In groups I and II, fentanyl (5 µg/kg IV) was administered before skin incision. When patients showed signs of insufficient analgesia, such as sweating, lacrimation, or a rise in mean arterial blood pressure or heart rate of >20%, or both, above preinduction levels, fentanyl (0.1 mg IV) was administered, followed by another dose if necessary. For postoperative analgesia, a continuous epidural infusion with 0.5% bupivacaine was started after the completion of surgery at a rate of 5 mL/h in group III patients. Postoperatively, patients in all groups received nicomorphine (10 mg IM) when they complained of pain, followed by another dose if necessary. All patients were confined to bed the first 24 h after surgery and did not receive chest physical therapy, breathing exercises, or incentive spirometry.

Assessments of pulmonary function were made with a commercially available portable respirometer (Dräger Spirotron, Lübeck, Germany). Measurements were made with the patients in a half-sitting position, with the head-up tilt at an angle of 45°. Forced vital capacity (FVC), peak expiratory flow, and forced expiratory volume in 1 s (Fev_1) were recorded the day before surgery and 2, 4, 8, and 24 h after surgery.

For determination of plasma cortisol and glucose, blood samples were obtained after induction of anesthesia, before incision, and at 30, 60, 120, and 240 min. Plasma was obtained by centrifugation and kept frozen at −20°C until required for assay. Cortisol levels were obtained through commercial radioimmunoassay (TDX, Abbott Laboratories, Diagnostic Division, Irving, Tex.). Coefficients of variation for this assay were 12.5% at 0.1 µmol/L, 6.6% at 0.4 µmol/L, and 5.7% at 1.1 µmol/L. Plasma glucose concentrations were analyzed by a routine glucose dehydrogenase method (EPOS Analyser 5060, Eppendorf, Hamburg, Germany). Coefficients of variation for this assay were 2.0% at 5.0 mmol/L and 2.5% at 10.0 mmol/L.

The degree of postoperative pain was assessed with a 0–10-cm visual analogue scale (VAS). Assessments were made when the patients arrived at the recovery ward and at 2, 4, 8, and 24 h.

Results are expressed as mean ± SD. Data were analyzed with one- and two-way analysis of variance for repeated measurements. When indicated, differences between baseline and subsequent means were compared with paired *t*-tests with Bonferroni correction for multiple comparisons. Opioid analgesic requirements and VAS scores were analyzed with the Wilcoxon signed rank test; *P* values <0.05 were considered significant.

Results

Demographic data of the patients in the three study groups are presented in Table 1. The groups were similar with respect to ASA classification, age, height, weight, and duration of the operation.

Ventilatory data are presented in Figure 1. The FVC was decreased in all groups up to 24 h after surgery. In group I, FVC decreased from 3.8 ± 0.42 to

Table 1. Clinical Characteristics in 30 Patients Undergoing Elective Cholecystectomy

Mean ± SD.

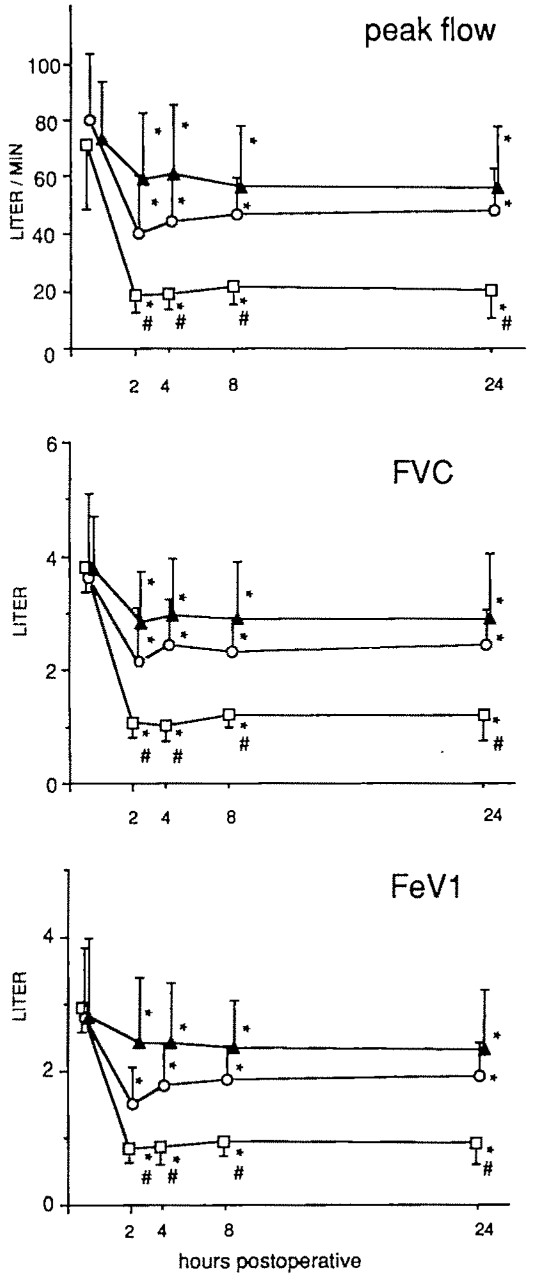

Figure 1. Ventilatory parameters before and after surgery. Values are mean ± SD. #$P < 0.05$ difference between group I (□) and groups II (○) and III (▲). *$P < 0.05$ decrease from preoperative values. Group I, cholecystectomy via subcostal incision; group II, laparoscopic cholecystectomy; group III, laparoscopic cholecystectomy with thoracic epidural analgesia; FVC, forced vital capacity; Fev_1, forced capacity volume in 1 s.

1.1 ± 0.27 L ($P < 0.01$), in group II from 3.6 ± 1.5 to 2.1 ± 0.94 L, and in group III from 3.8 ± 0.92 to 2.8 ± 0.90 L 2 h after surgery ($P < 0.05$). The reduction of FVC was significantly smaller in groups II or III compared with that in the CSI group ($P < 0.05$). Similar ventilatory changes were measured with Fev_1 and peak flow. There were no statistically significant differences between groups II and III. The ratio of Fev_1 to FVC remained unchanged.

Plasma cortisol increased significantly in all three groups compared with baseline levels ($P < 0.05$) (Figure 2). Peak cortisol concentration of 1.12 ± 0.22 μmol/L was reached in group III 120 min after induction of anesthesia. In contrast, maximal levels in groups I and II were reached 240 min after induction of anesthesia (1.23 ± 0.16 and 1.22 ± 0.22 μmol/L, respectively). At that time, cortisol concentration in group III was significantly lower than in groups I and II. Plasma glucose increased significantly in all three groups compared with baseline levels ($P < 0.05$) (Figure 2). Glucose concentrations reached maximal values in group I after 120 min (7.3 ± 0.67 mmol/L) and in group II after 240 min (7.7 ± 1.33 mmol/L). Glucose concentrations were significantly higher in group III at 30 and 60 min after induction compared with those in groups I and II ($P < 0.05$). In group III, a peak glucose level of 8.1 ± 1.59 mmol/L was measured at 60 min.

Opioid analgesic requirements during operation were similar in groups I and II. Patients in groups I and II received a total of 510 ± 184.2 and 510 ± 164.0 μg of fentanyl, respectively. Compared with groups I and II, significantly less fentanyl (265.0 ± 92.3 μg) was administered to patients in group III ($P < 0.05$). During the first 24 h after surgery, two patients in group III each received one dose of nicomorphine intramuscularly. Patients in groups I and II received significantly more nicomorphine during the first 24 h postoperatively ($P < 0.05$). Mean postoperative nicomorphine requirements in group I were 31.5 ± 14.8 mg and in group II 32 ± 17.8 mg. On arrival at the recovery room, VAS scores in group III were significantly lower compared with those of the two other groups ($P < 0.05$) (Figure 3). No significant differences were observed with respect to pain scores between the CSI and LPC groups at any time during the study. After 24 h, there were no significant differences among the three groups.

Discussion

The results of this study indicate that pulmonary function is significantly better after LPC than after CSI during the first 24 h postoperatively. Although we observed significant decreases of FVC after both techniques for cholecystectomy, the decrease of FVC in the laparoscopic groups was only half that of the CSI group. Unfortunately, we were unable to randomize our groups because the instrumentation for laparoscopic surgery was not always available; however, the groups were similar with respect to demographic data, suggesting that failure to randomize our groups did not influence the results of this study.

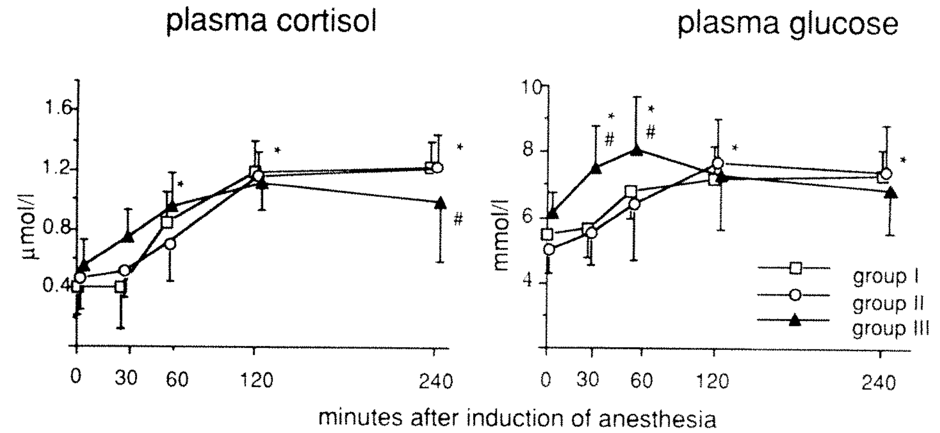

Figure 2. Metabolic endocrine response as measured by plasma cortisol and glucose. Values are mean ± SD. #$P < 0.05$ difference between group III and groups I and II. *$P < 0.05$ increase from preoperative values. Group I, cholecystectomy via subcostal incision; group II, laparoscopic cholecystectomy; group III, laparoscopic cholecystectomy with thoracic epidural analgesia.

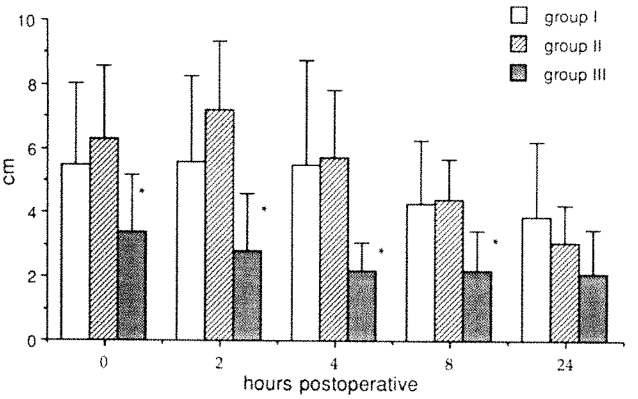

Figure 3. Visual analogue pain scores (0–10 cm) after surgery. *$P < 0.05$ difference between group I or II and group III. Group I, cholecystectomy via subcostal incision; group II, laparoscopic cholecystectomy; group III, laparoscopic cholecystectomy with thoracic epidural analgesia.

Because it has been shown that patients with chronic obstructive pulmonary disease are at risk of developing pulmonary complications after upper abdominal surgery (4), these patients may benefit from laparoscopic surgery. The combination of a general anesthetic technique with thoracic epidural analgesia for LPC did not significantly improve lung function further.

The mechanisms producing pulmonary deterioration after upper abdominal surgery are not completely understood. It appears that the type of incision plays an important role. Becquemin et al. (4) found that a midline incision caused significantly more pulmonary dysfunction than a transverse incision in patients with chronic obstructive pulmonary disease. Others reported that, given the same type of incision, postoperative pulmonary function was significantly better with smaller incisions than with larger ones (2). The data of our study confirm that a small incision results in better pulmonary function, because laparoscopic surgery involves only three minimal incisions.

Some investigators consider pain to be an important determinant of postoperative pulmonary dysfunction (3). However, even with good pain relief, lung function as measured by FVC and Fev_1 decreased to approximately 50%–60% of the preoperative value after abdominal surgery (8). Several studies indicated that epidural analgesia results in an average improvement of lung function of 15% compared with systemic analgesia (9,10). We did not study the effects of epidural analgesia on lung function in patients undergoing CSI. Therefore it is possible that the addition of epidural analgesia in patients with CSI would have resulted in better postoperative pulmonary function. However, even with a 15% improvement of lung function tests in patients undergoing CSI, these values would still be lower than those of patients undergoing LPC. In our study, pain assessments indicated that epidural analgesia improved analgesia in the postoperative period after LPC, but the differences in pulmonary function tests did not reach statistical significance. These findings are in agreement with those of Simonneau et al. (11) who demonstrated considerable postoperative impairment of diaphragmatic function after CSI that was not prevented by epidural analgesia.

A reduction of postoperative pain after laparoscopic surgery was reported by Dubois et al. (7); however, in that study postoperative pain scores were not reported. Our results do not support the contention that postoperative pain is diminished after LPC compared with CSI. The VAS pain scores and opioid analgesic requirements both during operation and postoperatively were not statistically significant between groups I and II. Although we did not assess the level of epidural analgesia postoperatively, we did confirm its effectiveness preoperatively with the pinprick method. In addition, analgesic requirements in the epidural analgesia group were significantly lower during the operation and during the first 24 postoperative hours compared with groups I and II.

Dubois et al. (7) also mentioned a rapid recovery with less surgical trauma after LPC. We expected that the metabolic endocrine response after LPC might be less pronounced than after CSI; however, our data show that the metabolic endocrine response after LPC is not diminished. The rapid recovery of patients after LPC is probably not due to effects of this technique on the metabolic endocrine response.

In a previous report (12), we observed peak levels of glucose and cortisol 150 min after CSI. Therefore we expected that in all groups, peak levels of cortisol would have been reached within 4 h after surgery. Data of this study show that there is a slight attenuation of the metabolic endocrine response in patients who received epidural analgesia, which becomes apparent 2 h after surgery. Because there are no data after 240 min, it is unclear whether this is a true diverging trend. Kehlet (5) could not demonstrate an effect of epidural analgesia on the metabolic endocrine response after major upper abdominal procedures. The higher glucose levels in the epidural group at 30 and 60 min are unexplained. High levels of catecholamines are known to produce higher glucose levels. Anxiety experienced by some patients during insertion of the epidural catheter or, alternatively, the resorption of the epinephrine from the local analgesic may have led to higher levels of cathecholamines. This may have resulted in higher glucose levels.

In conclusion, the endocrine metabolic response to surgery is not abolished after LPC under general anesthesia. Pulmonary function is significantly better after LPC than after CSI. There is no difference in pain after both surgical techniques. Thoracic epidural analgesia for laparoscopic surgery provides adequate pain relief but does not improve lung function after LPC.

Interscalene Brachial Plexus Block for Shoulder Surgery: A Proximal Paresthesia Is Effective

James J. Roch, MD, Nigel E. Sharrock, MB, ChB, and Ludmilla Neudachin, MB

Department of Anesthesiology, The Hospital for Special Surgery, Cornell University Medical College, New York, New York

This study was designed to determine whether the location of paresthesias is related to the success of interscalene blocks in providing anesthesia for shoulder surgery. Interscalene blocks were performed in 45 patients presenting for elective shoulder surgery. Interscalene injections of 33–55 mL of 1.5% mepivacaine with epinephrine were performed after the first elicited paresthesia to the shoulder, arm, forearm, or hand. In 20 patients (45%), the initial elicited paresthesia was to the shoulder, whereas in 25 patients (55%), the first parethesia was reported as distal to the shoulder. All patients developed brachial plexus anesthesia adequate for shoulder surgery. The time-course of onset of motor block as evaluated at the shoulder and elbow was not different between patients with shoulder paresthesias and those with more distal paresthesias. Handgrip strength was quantitatively evaluated with a dynamometer, and both paresthesia groups showed similar decrements in hand strength except at the end of the measurement period, when patients with distal paresthesias had a significantly weaker handgrip than patients with shoulder paresthesias. We recommend that paresthesias to the shoulder be accepted in performing interscalene blocks for patients undergoing shoulder surgery.

(Anesth Analg 1992;75:386–8)

The interscalene brachial plexus block is a widely used anesthetic technique for surgery of the shoulder and upper arm. In our experience, when this block is performed at the level of C-6, the earliest elicited paresthesia is often to the shoulder. It has been recommended widely in texts of regional anesthesia that shoulder paresthesias not be accepted as an indication that the needle tip is near the plexus and that further needle probing should be performed until a more distal paresthesia is achieved (1–4). Prolonged needle exploration in the neck in search of a distal paresthesia not only delays completion of the block but also may add significantly to patient discomfort. This investigation was undertaken to prospectively evaluate the relative success of interscalene block for shoulder surgery by means of a shoulder versus a more distal first-reported paresthesia.

Methods

After institutional approval, 45 unpremedicated patients (aged 17–79 yr) presenting for shoulder surgery were studied. Written, informed consent was obtained from all patients. Interscalene block was performed at the level of C-6 with a 23-gauge, 2.5-cm needle using a paresthetic technique described previously by Winnie (5). Patients were instructed to verbally identify the site of paresthesia as toward the shoulder, upper arm, elbow, forearm, or hand. At the first elicited paresthesia to the shoulder or more distally, patients received a standardized dose (10 mg/kg) of bicarbonated 1.5% mepivacaine with epinephrine (3 μg/mL). A paresthesia to the shoulder was classified as "proximal," whereas a paresthesia to the upper arm, elbow, forearm, or hand was classified as "distal."

Motor block was assessed by evaluating the patient's ability to elevate the upper arm at the shoulder, flex the forearm at the elbow, and perform a handgrip maneuver at baseline and every 2 min for 16 min after the interscalene injection. Motor block at the shoulder and elbow was qualitatively evaluated with a four-point scale: baseline motor ability was rated as grade 3; some demonstrable weakness was rated grade 2; marked weakness but with some retained antigravity ability was rated grade 1; and complete loss of antigravity ability was rated grade 0. Handgrip strength was quantitatively evaluated in all patients with a JAMAR dynamometer (JAMAR model 2A3, Asimow Engineering Co., Santa Monica, Calif.).

Proximal paresthesia	4.4 (±2.8) (range 2–10)	7.6 (±5.1) (range 2–16)	$P < 0.002$
Distal paresthesia	3.8 (±2.0) (range 2–8)	6.5 (±4.1) (range 2–16)	$P < 0.001$
	NS	NS	

NS, not significant.
Values are mean (±SD); paired *t*-test.

Patients received no sedation until completion of all measurements. Statistical analysis of data was done by analysis of variance, Scheffé F test, and paired or unpaired *t*-tests where appropriate.

Results

Forty-five interscalene blocks were performed. The first elicited paresthesia was observed to be proximal in 20 patients (45%) and distal in 25 patients (55%). There were no significant differences in age, height, weight, or gender between the proximal and distal paresthesia groups. After interscalene block, each patient developed adequate surgical anesthesia, and in no case was the block repeated or general anesthesia induced. The types of surgical procedures performed were similar in both groups (Table 1).

All 45 patients demonstrated complete loss of ability to elevate the upper arm at the shoulder (grade 0 motor ability) by 10 min after the block was administered. The mean time to achieve this degree of motor block was not different between the proximal and distal paresthesia groups ($P > 0.05$) (Table 2). Assessment of motor block at the elbow revealed that 44 of 45 patients had complete loss of ability to flex the forearm at the elbow against gravity by the end of the measurement period. The mean time to achieve this degree of motor block at the elbow was not different between the proximal and distal paresthesia groups ($P > 0.05$) (Table 2). The single patient who failed to achieve a complete motor block at the elbow by 16 min was in the proximal paresthesia group. By 2 min after the interscalene injection, this patient had a complete motor block at the shoulder and only grade 1 motor ability at the elbow; however, he retained weak antigravity motion at the elbow at the end of the measurement period. In both the proximal and distal paresthesia groups, motor block (grade 0 motor ability) at the shoulder significantly preceded motor block at the elbow (Table 2).

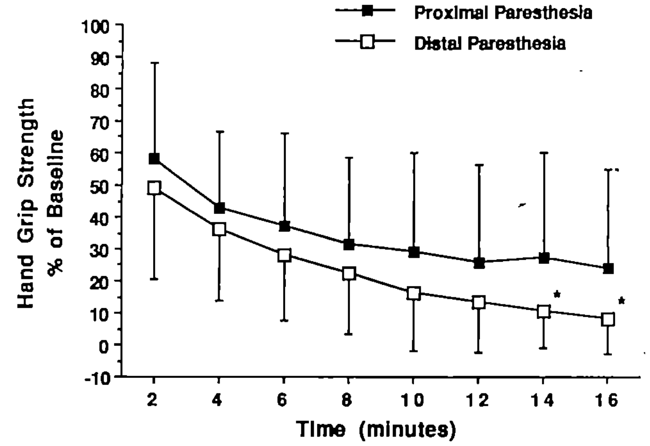

Figure 1. The decline in handgrip strength after interscalene block. Both proximal and distal paresthesia groups demonstrated decreases in handgrip strength by 2 min after block ($P = 0.001$), which continued to significantly decline through the measurement period ($P = 0.0001$; analysis of variance for two-factor repeated measures). Proximal and distal paresthesia groups had similar decreases in handgrip except at 14 and 16 min after block, when the distal paresthesia group demonstrated a significantly greater decrement in handgrip ($P = 0.03$; Scheffé F test). *$P < 0.02$ vs proximal paresthesia.

Handgrip strength was reliably reduced by 2 min after interscalene injection among all patients ($P = 0.0001$). The proximal and distal paresthesia groups showed similar reductions in handgrip strength throughout the measurement period except at 14 and 16 min after the injection, when the distal paresthesia group showed a significantly weaker handgrip than the proximal group ($P = 0.03$) (Figure 1).

Discussion

The most significant finding in our study is that each interscalene block performed after the elicitation of a shoulder paresthesia resulted in profound brachial plexus anesthesia. The explanation most commonly cited as to why shoulder paresthesias are unacceptable is that such a proximal paresthesia could theoretically result from needle stimulation of the suprascapular nerve after it has exited the fascial sheath that envelops the brachial plexus (4). If this occurs, any local anesthetic deposited would be expected to result in a selective block of the suprascapular nerve. Because the suprascapular nerve has no cutaneous innervation and provides motor innervation only to the supraspinous and infraspinous muscles, such a block would be easily discernible from a brachial plexus block. In the present study, when shoulder paresthesias were accepted such a selective blockade of the suprascapular nerve was never observed to occur.

The observation that 45% of initial paresthesias were to the shoulder underscores the clinical relevance of evaluating the reliability of proximal paresthesias when interscalene blocks are performed. Because we looked solely at the initial elicited paresthesia, a necessary conclusion is that in our study, almost half of the interscalene blocks were successfully completed more quickly because we accepted a shoulder paresthesia rather than continuing to pursue a more distal paresthesia. In addition, because multiple needle insertions may possibly result in nerve trauma, one may speculate that by accepting a proximal paresthesia and avoiding prolonged needle probing, the patient may be exposed to a reduced risk of postinjection nerve damage.

For this study, mepivacaine was used for interscalene blocks, because we have found this local anesthetic provides adequate duration of anesthesia for most shoulder procedures as well as rapid return of function after surgery. Because much of our shoulder surgery is performed on an ambulatory basis, this allows for early postoperative assessment of nerve function as well as determination of adequacy of pain relief before discharge. Although the dose of mepivacaine used was relatively large (10 mg/kg), we have found this to be a safe and effective dose for brachial plexus blocks, as have other authors (6).

In this study, we assessed brachial plexus block by evaluating the onset of motor rather than sensory blockade to allow us to use an objective measure of neural blockade (the dynamometer). In addition, because motor blockade often precedes sensory blockade (7), monitoring motor function allowed rapid completion of our measurements so as to minimize delay in preparation of patients for surgery. The observed sequential onset of motor blockade from proximal to more distal musculature has been described previously (8). The fact that there was little difference in the time-course of motor blockade between the proximal and distal paresthesia groups is compatible with the concept that in both situations, local anesthetic was deposited within the fascial sheath at approximately the same level (C-6). The slight difference in measured handgrip strength between the proximal and distal paresthesia groups near the end of the measurement period is not easily explained. It is possible that a more profound distal block results after a distal paresthesia and that this could have clinical implications when interscalene blocks are performed for more distal surgical procedures.

In summary, it was observed that during the performance of interscalene brachial plexus blocks, almost half of the initial elicited paresthesias were toward the shoulder and that in all cases, use of these proximal paresthesias resulted in brachial plexus anesthesia, which was satisfactory for shoulder surgery. We therefore recommend that paresthesias toward the shoulder be accepted in the performance of interscalene blocks for surgical procedures involving the shoulder.

Influence of Volume on the Spread of Local Anesthetic-Methylene Blue Solution After Injection for Intercostal Block

S. S. Moorthy, MD, Stephen F. Dierdorf, MD, and Peter B. Yaw, MD

Departments of Anesthesia and Surgery, Indiana University School of Medicine, Richard L. Roudebush Veterans Administration Medical Center, Indianapolis, Indiana

---

The purpose of this study was to evaluate the influence of the volume of methylene blue-local anesthetic on the spread of the injectate along the costal pleura. Twenty patients undergoing elective thoracotomy were studied. Twelve patients received intercostal nerve injection with 10 mL of 0.5% bupivacaine with methylene blue (10-mL group), and eight patients received 5 mL of 0.5% bupivacaine with methylene blue (5-mL group). The area of spread of the methylene blue was measured after the pleural cavity was incised. The 10-mL group had a mean area of spread of 51.1 cm^2 as opposed to 17.6 cm^2 for the 5-mL group ($P < 0.05$). In the 10-mL group, eight patients had bupivacaine-methylene blue spread to two intercostal spaces, three patients to three intercostal spaces, and one patient to four intercostal spaces. In the 5-mL group, seven patients had bupivacaine methylene blue spread confined to one intercostal space and one patient to two intercostal spaces. We conclude that a potential anatomic space exists between the costal pleura and the internal intercostal muscle and that the spread of local anesthetic after intercostal nerve block injection is volume dependent.

(Anesth Analg 1992;75:389–91)

Intercostal nerve block with local anesthetic solutions is indicated for reducing pain after thoracotomy and upper abdominal surgery, after rib fracture, and in the treatment of intercostal neuralgia. The block can be achieved by a single injection, multiple injections, and continuous catheter techniques; however, there is controversy with regard to the effect of the technique on spread of the solution. The spread of local anesthetic after intercostal nerve block has been studied in both patients and cadavers (1,2). Although there has been a suggestion that volume may affect the spread of local anesthetic, the comparative volumes have been small (3 and 5 mL) (1,2). There is also the possibility that because of autolysis, spread in the cadaver may be greater than in the patient (3). Spread of local anesthetic cephalad and caudad from the injection site would suggest that a potential anatomic space exists between the costal (parietal) pleura and internal intercostal muscles. This potential space is not identified as such in standard anatomy textbooks (4). A number of recent studies in anatomic specimens and volunteers demonstrated that the spread of the injected solution is confined to one intercostal space (5) or to multiple spaces (6,7). These differences could be related to whether the needle tip is superficial or deep to the internal intercostal muscle. In the present study we sought to evaluate, in live subjects, the relationship between two volumes (5 and 10 mL) of injectate and the spread of local anesthetic mixed with methylene blue after intercostal nerve block. This study attempted to answer two questions. First, can multiple intercostal nerve blocks be achieved with a single injection? Second, does a potential anatomic space exist between the costal pleura and the intercostal muscles?

Methods

After approval by the Indiana University Committee for Protection of Human Subjects and informed patient consent, 20 patients undergoing elective thoracotomy were studied. All patients received general anesthesia consisting of thiopental (4 mg/kg IV) for induction, either vecuronium (0.1 mg/kg IV) or succinylcholine (1.5 mg/kg IV), tracheal intubation, and inhaled isoflurane and nitrous oxide in oxygen. After the initiation of anesthesia, each patient was positioned in the appropriate lateral decubitus position for thoracotomy. Before the surgical incision, 0.5% bupivacaine with methylene blue was injected into the intercostal space two interspaces caudad to the proposed surgical incision. Eight patients received

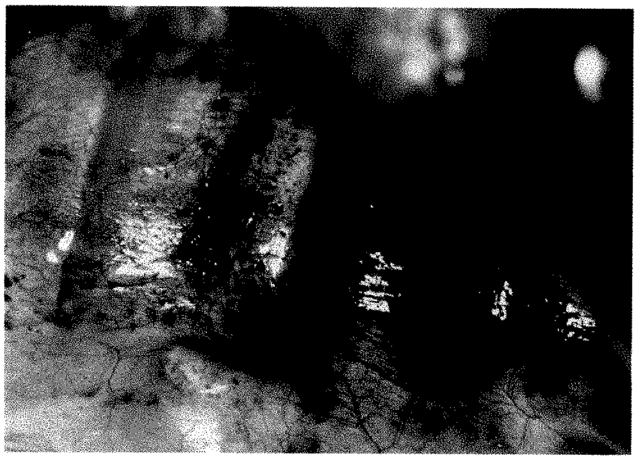

Figure 1. Photograph of the costal pleura demonstrating spread of methylene blue across three intercostal spaces after a single intercostal injection with 10 mL of 0.5% bupivacaine with methylene blue. Injection of the solution was performed at the angle of the rib, near the central part of the coloration. The spread of methylene blue was in all directions.

5 mL of bupivacaine with methylene blue, and 12 patients received 10 mL of bupivacaine with methylene blue. The intercostal injection was performed with a 2-in. 22-gauge needle at the posterior angle of the rib 8 cm from the dorsal midline. The needle was directed 45° in the cephalad direction. After the inferior margin of the rib was contacted, the needle was advanced 3 mm beyond the rib. At that point, the needle was fixed and the bupivacaine-methylene blue solution injected. After the intercostal injection, the surgery was begun. After the pleural cavity was exposed, the surgeon (unaware of the volume of injectate) measured the length and width of the spread of the methylene blue. The time from injection to measurement of the area of spread was approximately 30 min. The area of the spread was calculated from the length and width of the stained area. The number of intercostal spaces discolored were counted. Statistical comparisons of the area of spread and the number of intercostal spaces traversed were performed. Statistical analysis used the Wilcoxon signed rank test and two-sample *t*-test. A *P* value <0.05 was considered significant.

Results

Seven of the eight patients who received 5 mL of bupivacaine-methylene blue had the injectate confined to one intercostal space. Of the 12 patients receiving 10 mL of bupivacaine-methylene blue, eight had spread to two intercostal spaces, three had spread to three intercostal spaces (Figure 1), and one had spread to four intercostal spaces. The patients receiving 10 mL had a mean area of spread of 51.1 ± 19 (SD) cm^2 as opposed to 17.6 ± 7.6 cm^2 ($P < 0.05$) (Table 1). There was no evidence of a preferential medial spread to the paravertebral region. The solution spread medially, laterally, superiorly, and inferiorly from the point of injection.

Table 1. Spread of Local Anesthetic After Intercostal Nerve Block and Area of Staining of Costal Pleura With Methylene Blue

	10-mL Injectate (n = 12)	5-mL Injectate (n = 8)
Width (cm)	6.0 ± 1.5	2.2 ± 1.7

[b] $P < 0.02$.

Discussion

This study demonstrates that the spread of local anesthetic-methylene blue after intercostal injection is volume dependent. In general, a volume of 5 mL is confined to one intercostal space, whereas 10 mL will spread to multiple intercostal spaces.

Other studies have demonstrated some cephalad-caudad spread, but those studies used smaller volumes injected into cadavers. Nunn and Slavin (1) injected 3 mL of India ink into anatomic cadaver preparations and found spread cephalad and caudad involving the intercostal space above and below the injection space. Moore (2) also demonstrated lateral and medial spread after intercostal injection of India ink into cadavers. Moore did not observe cephalad or caudad spread of the dye in most of the specimens. This difference between the studies of Nunn and Slavin (1) and Moore (2) might be explained by size of the needle bevel. A longer bevel is associated with spread of the injectate into more fascial planes. The use of cadavers also introduces the possibility of artificial tissue planes produced by tissue autolysis after death.

In a study of live subjects, Moore et al. (3) injected 5 mL of radiographic dye into the intercostal space and observed spread in all four directions. Mowbray and Wong (8) injected 3 mL of bupivacaine with methylene blue into both patients and cadavers. The solution was confined to one intercostal space in 86% of the patients and 84% of the cadavers. Some of the patients in the Mowbray and Wong study did, however, demonstrate spread to more than one intercostal space. In these studies the actual degree of neural blockade was not specifically discussed. Studies injecting radiopaque dye with the local anesthetic demonstrated localization to one intercostal space in some patients and spread to multiple intercostal spaces in other patients (6,7). The spread of the dye-local anesthetic solution in our study resembles the spread demonstrated by Crossley and Hosie (6) in a radiologic study. The use of 10 mL of solution in our study produced spread in all directions. There was no preferential medial spread.

Our study demonstrates conclusively that the spread of local anesthetic after intercostal nerve block is volume dependent. Spread in the space between the costal (parietal) pleura and the intercostal muscles depends on proper placement of the needle. The needle should be advanced 3 mm beyond the inferior rib margin to ensure proper deposition of the local anesthetic to facilitate spread. If the needle is too shallow, then the local anesthetic will be confined to one intercostal space. Although our study addresses intercostal spread, the extent of local anesthesia produced was not measured.

Our finding is of clinical significance, because multiple intercostal nerves can possibly be blocked with one injection. This technique can therefore be useful in postoperative analgesia. We have not studied this technique in patients who have a disruption in the parietal pleura (e.g., neoplasm). It is conceivable that in patients with a disrupted pleura, spread of the local anesthetic solution will be restricted. Further clinical studies are warranted in a variety of different clinical situations. A clinical study correlating the degree of intercostal spread with analgesia is also justified. Johnson et al. (9) demonstrated multiple segmental intercostal nerve block by using a continuous catheter technique in the paravertebral region; however, our study addresses the issue when the local anesthetic solution is injected with the conventional single injection technique. The complications associated with intercostal nerve block, such as toxic reactions from rapid absorption of local anesthetics and epinephrine, pneumothorax, and hypotension secondary to paravertebral sympathetic blockade, can occur with any technique. However, a larger volume single injection is not associated with more rapid absorption than multiple injections as long as the total local anesthetic dose is not excessive.

In summary, we have demonstrated that a potential anatomic space does exist between the costal pleura and the internal intercostal muscle and that a local anesthetic-methylene blue solution will spread to multiple intercostal segments. This finding suggests the possibility of achieving multiple intercostal nerve blocks with a single injection of 10 mL of local anesthetic, thereby decreasing the incidence of, or avoiding complications associated with, multiple intercostal injections. Further work in volunteers with this technique is required to determine the number of dermatomes anesthetized.

Repeated Intrathecal Injections of Dezocine Produce Antinociception Without Evidence for Neurotoxicity in the Rat: A Study of Morphometric Evaluation of Spinal Cord Histology

Björn A. Svensson, MD, PhD, Liisi Alari, MPharm Sci, and Claes Post, PhD

Departments of Anatomy and Pharmacology, Uppsala University, Uppsala, and Astra Pain Control AB, Södertälje, Sweden

This study was designed to determine the antinociceptive and spinal cord histologic effects of a new agonist/antagonist opioid drug dezocine. This drug was injected intrathecally in rats at a dose of 50 or 125 μg twice daily for 14 days. The tail-flick test showed that the antinociceptive effect declined gradually, with no detectable effects by day 14. Quantitative histologic techniques and light and electron microscopy showed that neither dose, compared with vehicle, created any morphologic changes in the spinal cord that could be attributed to a neurotoxic or otherwise degenerative effect of the drug. In conclusion, dezocine is a drug that gives rise to sustained antinociceptive effects when administered intrathecally and causes no morphologic changes in the rat spinal cord that could be indicative of neurotoxic potential.

(Anesth Analg 1992;75:392–9)

Intrathecal or epidural administration of opioid analgesic drugs has become increasingly used for treating patients with pain. The analgesia is produced by activation of opioid receptors located in the dorsal portion of the spinal cord (1). When injected intrathecally, morphine inhibits release of primary afferent substance P (2) and also hyperpolarizes the secondary dorsal horn neuron (3) receiving the nociceptive afferent. With repeated injections of morphine, the antinociceptive effect declines both clinically (4) and experimentally in animal models of nociception (5).

Dezocine is a new analgesic drug, recently introduced clinically for systemic administration. Its profile is that of a mixed opioid agonist/antagonist, with antinociceptive effects found in animals after systemic injection (6). This class of opioids may potentially have advantages over traditional full agonist opioids, with slower development of tolerance and possibly a lesser extent of supraspinally mediated respiratory depression. This profile may warrant spinal cord administration of dezocine. Recently, however, dezocine was reported to have deleterious effects in the spinal cord in dogs after repeated administration (7). However, the investigational procedure used by those authors gave rise to profound morphologic changes in both control and dezocine-treated animals, suggesting that the model may not be well suited for such studies.

The aim of the present investigation was to study the effects on nociceptive behavior in animals after intrathecal administration of dezocine, both after short-term and repeated dosing, and to ascertain the morphology of the spinal cord after such treatment.

Methods

After approval by the regional animal ethics committee, male Sprague-Dawley rats (Alab, Sollentuna, Sweden), weighing 320–350 g, were kept in animal rooms thermostatically maintained at 21 ± 1°C and a regulated dark-light environment (lights on at 6 AM and off at 6 PM). The rats were housed on sawdust bedding material in groups of five for at least 5 days before surgery. After the surgery and until termination of the experiment, the rats were housed in individual cages. They had free access to standard

food pellets and tap water throughout the experiment.

Three milliliters per kilogram of an aqueous solution containing (per 100 g) chloral hydrate, 4.25 g; ethanol, 9 g; propylene glycol, 42.8 g; sodium pentobarbital, 0.98 g; and magnesium sulfate, 2.1 g (Apoteksbolaget, Stockholm, Sweden) was administered intraperitoneally to anesthetize the animals. The doses of dezocine HCl (Astra Pain Control AB, Södertälje, Sweden) were calculated as salt.

Preparatory surgery for intrathecal injections was performed during equithesine anesthesia. A polyethylene catheter (PE-10, Clay Adams), previously streched to double length, was inserted into the spinal subarachnoid space through a slit in the atlantooccipital membrane (8). The length of the catheter (8.5 cm) was chosen to place the catheter tip at the L-1 region of the lumbar enlargement. Only rats demonstrating normal motor behavior by a global assessment after surgery were included in this study.

Tail-flick testing (9) was performed with an IITC Inc. model 33 analgesimeter. During testing, a rheostat-controlled light beam was focused on the tip of the tail, and the time interval from the onset of the heat stimulus to the flick of the tail was recorded. A cutoff time of 15 s was used to avoid tissue destruction. Three days after surgery, the rats were habituated to a restraining tube used for tail-flick testing at three consecutive 10-min sessions. One week after surgery, the experiment was started. Each group contained seven to eight rats.

The drugs were administered dissolved in 10 μL of 0.9% saline solution, followed by 15 μL of 0.9% saline solution to flush out the catheter. After the injections, a 0.26-mm-diameter plastic plunger was inserted into the PE-10 catheter as a stopper. Dezocine HCl (50 or 125 μg) or 0.9% saline solution was administered through the intrathecal catheters at 8 AM and 4 PM each day for 14 days. The smaller dose was chosen to ascertain complete analgesia. To determine any possible neurotoxic effect, the strongest concentration that could be made (12.5 mg/mL) was also tested. Tail-flick testing was performed each day before (predrug latency) and 30 min after the 8 AM intrathecal injection.

Twenty-four hours after the last intrathecal injection of saline solution or dezocine, the rats were reanesthetized with the same drug and killed by transcardial perfusion with 200 ml of Tyrode's solution (38°C, pH 7.4) containing 10,000 E heparin per liter followed by a 500-mL mixture of 2% glutaraldehyde and 1% formaldehyde in 0.1 M phosphate buffer (38°C, pH 7.4). The perfusion was continued for approximately 20 min (10). The spinal cord was removed together with the catheter after bilateral laminectomy of the spine.

Under a dissection microscope, the L-1 segment was excised. It was stored for 12 h in cold fixative (4°C). Only animals with the tip of the catheter at the level of the L-1 segment verified under the microscope were included in the study. The L-1 segment was rinsed in the buffer and then serially sectioned by means of a vibratome. Thereafter, the vibratome sections were rinsed in a 0.1 M sodium cacodylate buffer (pH 7.4), postfixed for 30 min in 2% OsO_4 dissolved in cacodylate buffer, and dehydrated in graded ethanol and embedded in a epoxy resin (Agar 100) between Teflon-sprayed slides and 100-μm-thick acetate foils (11). After the sections were examined with the light microscope, five random tissue blocks containing the dorsal horn of the spinal cord were excised from each animal and reembedded for fine sectioning (2 μm). For electron microscopy, ultrafine sections (500 Å) were made from both the ventral and dorsal horns. The fine sections were stained with toluidine blue and the ultrathin sections with uranyl and lead citrate.

The fine sections were used for quantitative analysis of the dorsal horn morphology (12–14). The variation in total cell number (per mm^3), dark cell number (interpreted as inflammatory cells) in laminas I–III of each section, mean cell volume (μm^3), and cell ratio (%) in a reference volume of the dorsal horn were used as sensitive variables of spinal neurotoxicity. The reference volume contained laminas I–III of a rostrocaudal column throughout the whole L-1 segment. It was measured in each animal according to the Cavalieri principle (15). With the light microscope, the outlines of the transverse area of the reference volume were drawn with the aid of a drawing tube attached to the microscope. By means of a graphic pen-data tablet device (MOP, Kontron), that area was measured. The sections used were spaced through the L-1 segment with an intervening distance of at most 0.1 mm. We found the length of the L-1 segment by serial planimetry of the total number of the L-1 sections to constitute approximately 3.1% of the total length of the spinal cord. Thus, the length of the spinal cord was measured in each animal, and the length of the L-1 segment was calculated.

The number of cells within the reference volume (V_{ref}) was calculated according to the disector principle (16). A disector (V_{dis}) is a small tissue block in the reference volume. On a section, the outlines of the area of the disector were drawn with the drawing tube. In that area the cell nucleoli of the neurons were sampled, and the cells were drawn. This particular area was then sought on the next serial section and the cell nucleoli of the drawn cells not sectioned by this "sought" section were counted (Q). Within each animal, 30 disectors, all the same size, were sampled

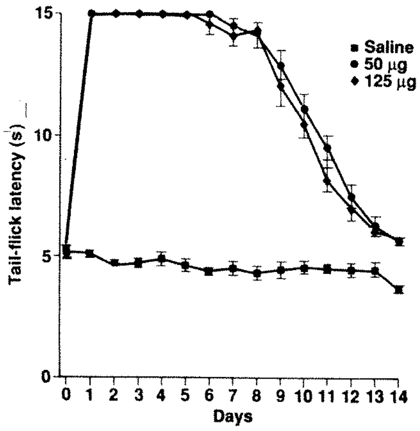

Figure 1. Antinociceptive effects measured in the tail-flick test of dezocine (50 or 125 μg) and saline solution after twice-daily intrathecal administration. Tail-flick latencies were measured each day after the first daily dose. The cutoff time was 15 s. Results are expressed as mean ± SEM ($n = 7$).

from the reference volume. The coefficient of error was estimated by splitting this sample into two groups (12). A coefficient of error <0.05 was statistically accepted for the sample frame.

A systematic random sample of sections was analyzed in each animal, and the number of cells (N) in the reference volume was calculated according to the formula $N = \Sigma\, Q\cdot V_{ref}\cdot V_{dis}^{-1}$. The mean cell volume was calculated from the total cell volume and total cell number within the reference volume. The total cell volume was estimated by point-counting as the ratio between the area of the cell bodies and the area of the disectors (17). The cell number (N) was then normalized to cell number per cubic millimeter for comparison among the animals. The values for total cell number, the number of dark cells, mean cell volume, and cell ratio were compared with control values. Student's *t*-test was used to test for significant differences, and a probability of <0.05 was accepted as statistically significant.

The neuronal tissue of the L-1 segment was examined with the electron microscope for signs of toxicity with respect to karyolyses, edema, and the general appearance of the mitochondria, microtubules, neurofilaments, and synaptic vesicles. The preservation of the tissue as well as the myelin damage was also studied. Occasional splits of the myelin sheets were accepted because this can also be seen in untreated neuronal tissue.

Results

Intrathecal administration of 50 μg of dezocine (Figure 1) in rats induced an antinociceptive effect in the tail-flick test that reached the 15-s cutoff value 30 min after the first injection. No signs of tolerance were seen until after approximately 1 wk of twice daily injections, when the antinociceptive effect started to diminish. Even at the termination of the experiment, there was still some antinociceptive effect seen in the dezocine-treated rats compared with the saline solution-treated animals. When 125 μg of dezocine was administered twice daily, the antinociceptive effect and tolerance development were similar, as with the smaller dose. Intrathecal administration of 0.9% saline solution did not induce any antinociceptive effect during the experiment, but there was a minor decrease in the tail-flick latency after 14 days of treatment.

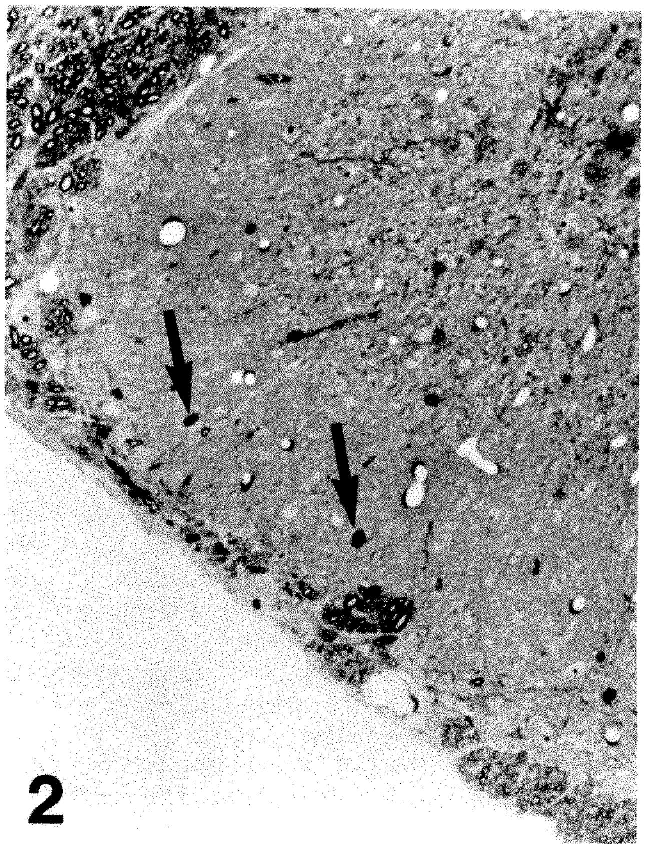

Figure 2. Light micrograph of a toluidine-stained plastic-embedded section from lumbar spinal cord (L-1 segment) after intrathecal injection of saline solution for 14 days. Normal findings (rat S2 [Table 1]). Note the presence of dark inflammatory cells (*arrows*). ×450.

No effect on general behavior, such as an effect on the motor system or weight loss, was noticed after the smaller dose. After the larger dose, some activation of locomotion was seen as well as rearing, grooming, and jumping.

In three of the rats, a mild inflammatory reaction was seen along the course of the catheter. In that area, dark cells were frequently observed. These cells

Figure 3. were interpreted as the inflammatory cells. No significant differences were noticed between the rats injected with dezocine and the untreated control rats with respect to tissue reaction. Thus, dark inflammatory cells could occasionally be observed in the gray matter of both groups (Figures 2 and 3). They were scattered throughout the ventral and dorsal horn. The neurons of the dorsal horn and the ventral motor neurons (Figure 4) had the same appearance in the dezocine-injected rats as was observed in the control rats. The spinal tracts demonstrated no visible signs of injury or spongy appearance of the myelin sheets.

Quantitative Investigations

The calculations of the reference volume revealed no statistically significant differences between the control animals (0.75 ± 0.034 mm^3) (mean ± SEM) and the rats injected with 50 μg of dezocine (0.69 ± 0.037 mm^3) or 125 μg of dezocine (0.68 ± 0.035 mm^3). In all of the rats, the reference volume ranged between 0.52 and 0.89 mm^3. The total number of cells per cubic millimeter in laminas I–III of the dorsal horn, as well as the number of dark (inflammatory) cells, demonstrated no significant differences between the control and the dezocine-injected animals. The individual values (means ± SEM) are shown in Table 1. Furthermore, the ratio of neuronal cell bodies in the reference volume was 5.2% (mean) for the saline solution-injected rats, which was slightly higher than the mean value of 5.0% for the rats injected with dezocine. This difference, however, was not statistically significant.

The calculations of the mean cell volume from the values of total cell volume in the reference volume and the total number of cells revealed no statistical differences between the saline solution- and the dezocine-injected rats. Likewise, the mean cell volume reached a higher value in the control (620 ± 20 μm^3) (mean ± SEM) than in the dezocine-injected animals. The corresponding values for these two groups were 610 ± 20 and 580 ± 20 μm^3, respectively (mean ± SEM). The coefficient of error demonstrated $P < 0.05$ for both the control and the dezocine-injected animals.

Electron Microscopic Observation

With the electron microscope, no morphologic differences could be detected between the saline solution- and dezocine-injected animals. The cell bodies of the neurons demonstrated normal shapes (Figure 5). Their cell membranes were intact, and the nuclei were seen in the typical central position with a distinct nucleoli. The organelles of the neurons were normal in appearance as well. Furthermore, the microtubuli, neurofilaments, and mitocondria of the axons displayed normal morphology. The boutons contained small, round vesicles.

The dark cells observed with the light microscope of both saline solution- and dezocine-injected rats were identified as microglial cells with prominent perikarya (Figure 6). They were scattered throughout the neuropil of the dorsal and ventral horns. Adjacent to the microglial cells, no degenerating cell bodies, axons, or boutons were found. Neither could phagocytosed cells be seen in the gray matter.

The perivascular cells and perivascular astrocytes also demonstrated normal morphology. Occasionally, the perivascular astrocytes contained round and sometimes even irregularly shaped dense granules (Figure 7). The myelin sheets sometimes showed concentric splits but without any visible differences between the control and dezocine-injected animals. Finally, preservation of the tissue was generally good.

Discussion

The present investigation demonstrates that dezocine is a drug that exerts antinociceptive effects when administered intrathecally to rats and that tolerance develops at a considerably slower rate than has been reported in the literature for morphine (5). We have also found that the spinal cord when examined postmortem shows no signs of neurodegenerative or other effects indicating that dezocine may be toxic.

The method used (i.e., a combination of light and electron microscopic observations with a quantitative morphometric method) has increased the sensitivity of investigations of neurotoxicology (14). After repeated injections of substance P, guanfacine, and somatostatin, light microscopic observations revealed toxic reactions of the nervous tissue (18–20). Interpretation of these limited data is difficult because the identity of the cells affected cannot be determined, especially with respect to the occurrence of microglial cells.

In the present study, there were no significant differences between the number of cells per cubic millimeter in the dorsal horn of the control rats (85,000) and those rats injected with either 50 μg (87,000) or 125 μg (83,000) of dezocine. These values are in accordance with the mean number of cells found in nonsurgical rats (14). The presence of a small number of the microglial cells in both the saline solution- and dezocine-injected rats was interpreted as a normal phenomenon in neuronal tissue. Another explanation for the occurrence of the microglial cells may be the tissue preparation; however, this seems unlikely, because the electron microscopic analysis demonstrated well-preserved tissue. In electron microscopic studies of normal nerve tissue, microglial cells have been found in small numbers with typical morphology (21,22). After lesioned axons, they ap-

peared in increased numbers and were often located near degenerated structures (22).

The morphometric method, which uses the "disector principle," requires no assumptions about the shape of the investigated cells and is an unbiased stereologic estimator of total cell number and mean cell volume (12). The reference volume was measured in each animal (14) so that it was possible to estimate the total cell number and mean cell volume independently of tissue swelling or shrinking caused by the fixation, dehydration, or plastic embedding of the vibratome sections. Finally, the mean cell volume, which may be the most sensitive variable to detect minor neurotoxicologic reactions of the nerve cells (such as variation in cell volume), demonstrated no significant differences between the saline solution- and dezocine-injected animals. This is in accordance with the values found in normal rats transcardially perfused with the same mixture of glutaraldehyde and formaldehyde used in this study (14).

The L-1 segment most adjacent to the tip of the catheter, where the concentration of dezocine would be the highest after the injections, showed no degenerated or phagocytosed cells at the electron microscopic level. Such morphologic changes would have been an expected sign of neurotoxicity or neurode-

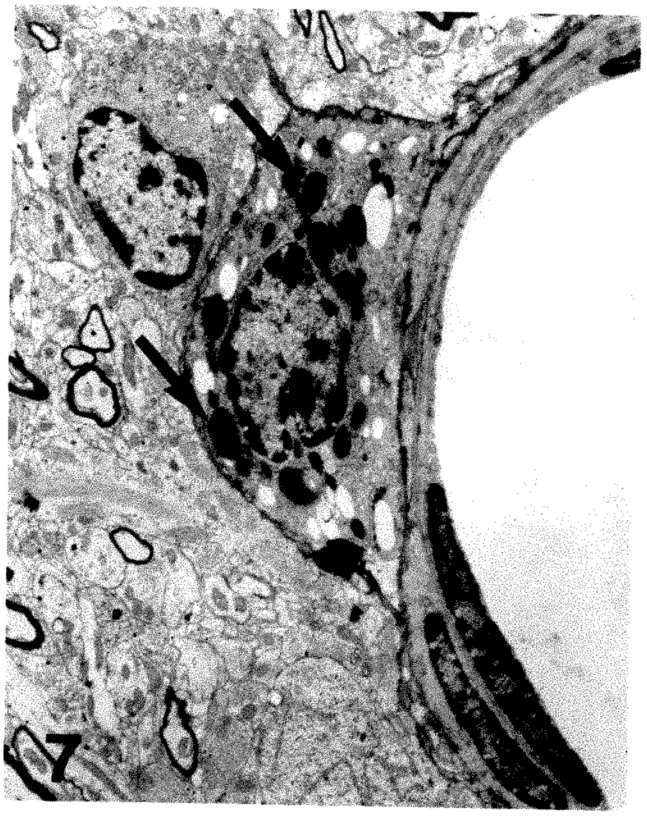

Figure 7. Electron micrograph of perivascular cells in the ventral horn (rat D8, intrathecal dezocine, 125 μg [Table 1]). The astrocyte contains oval, dark inclusions and vacuoles (*arrows*). The pericyte, as well as the neuropil adjacent to the vessel, shows normal morphology. ×24,500.

generation from other causes. The morphologic study was performed on the L-1 segment, because it was previously shown that this does not undergo any structural artifacts caused by injection (18,23). We previously found that the mild inflammatory reaction that may occur in close proximity to the catheter has no influence on morphology elsewhere in the spinal cord (14,23); however, Coombs and coworkers (7) found extensive fibrosis and inflammatory reactions after spinal administration of both saline solution and dezocine in dogs. The exact cause of the degeneration could not be established, but severe leptomeningeal reactions in both control and drug-injected animals seem to limit the value of repeated intrathecal injections in dog models for assessment of spinal drug toxicity.

In conclusion, repeated intrathecal administration of dezocine causes an antinociceptive effect that undergoes tolerance at repeated twice-daily injections; however, this tolerance develops more slowly than that previously reported for morphine (5). When injected twice daily over 14 days, dezocine produced no toxicologic effects in the rat spinal cord, as determined by quantitative analysis and light and electron microscopic observations. Dezocine may thus have clinical potential as a spinally administered drug for treatment of certain severe pain states.

We thank Kärstin Flink and Ingmarie Olsson for skillful technical assistance.

Effects of Interpleural Bupivacaine (0.5%) on Canine Diaphragmatic Function

Stephen E. Kowalski, MD, FRCPC, Barry D. Bradley, MD, Roy A. Greengrass, MD, FRCPC, Jeff Freedman, and Magdy K. Younes, MD, FRCPC

Departments of Anesthesia and Respiratory Medicine, University of Manitoba, Winnipeg, Manitoba, Canada

Several authors have questioned the potential for phrenic nerve paralysis with interpleural analgesia. This study was designed to examine the potential for phrenic nerve paralysis with the use of interpleural bupivacaine in dogs. Seven dogs were anesthetized, tracheally intubated, and allowed to breathe spontaneously with halothane/oxygen while in the supine position. After a midline laparotomy, two wires were inserted into the costal portion of each hemidiaphragm for measurement of electromyographic (EMG) signals. A balloon catheter was placed in the abdominal cavity to measure abdominal pressure. The abdomen was then closed. Airway pressure was measured through a side port in the endotracheal tube. Bilateral interpleural catheters were inserted with the loss-of-resistance technique. Each dog was used for two experiments, one on each side, except for one animal. To assess the contribution of the ipsilateral diaphragm to total respiratory effort, the airway was occluded at functional residual capacity for three consecutive breaths, and EMG, airway pressure, and abdominal pressure were measured. In five of nine experiments with bupivacaine, there was complete loss of EMG activity on the side of the injection. In two dogs, there was partial loss of diaphragmatic function, and in the remaining two, there was no change in EMG. In the normal saline solution group ($n = 4$), there was no change in the EMG. Two dogs that received bilateral bupivacaine injections developed paradoxical respiration with negative inspiratory intraabdominal pressures. Phrenic nerve paralysis or paresis can occur with interpleural blockade. The factors affecting the occurrence of this complication remain to be elucidated.

(Anesth Analg 1992;75:400–4)

Interpleural administration of local anesthetics provides excellent postoperative analgesia for unilateral surgical procedures, such as cholecystectomy via a subcostal incision, mastectomy, or thoracotomy (1–5). Bilateral interpleural catheters have also been used to provide analgesia for major thoracoabdominal procedures (6). Initial reports concerning interpleural analgesia showed a beneficial effect on postoperative pulmonary function (2,4,7). More recent clinical studies have questioned this beneficial effect and have shown no improvement in postoperative forced vital capacity (FVC) and forced expiratory volume in one second (FEV_1) despite improvement in postoperative pain scores (8,9). The reason for the lack of improvement in postoperative spirometry is not known, but one of the hypotheses is that phrenic nerve paralysis may occur with interpleural administration of local anesthetics (8,10,11).

The purpose of this study was to examine the effect of interpleural bupivacaine on diaphragmatic function and to determine whether diaphragmatic paralysis can occur with this technique.

Methods

Seven mongrel dogs, weighing between 15 and 25 kg, were studied. The animals were anesthetized with thiopental (10 mg/kg) and their tracheas intubated with a 9-mm internal diameter endotracheal tube. The dogs were allowed to breath spontaneously, and anesthesia was maintained with 1% halothane in oxygen, delivered via a calibrated Fluotec vaporizer. Femoral venous and arterial lines were inserted for administration of intravenous fluids and blood gas determinations. A midline laparotomy was performed, and two wires were inserted parallel to one another into the costal portion of each hemidiaphragm to measure diaphragmatic electromyographic activity (EMG). The wires used were Ethicon cardiac pacemaker wires, which have an uninsulated distal portion that was inserted into the muscle and

an insulated portion that was passed out through the abdominal wall. A balloon catheter was placed in the abdomen for measurement of intraabdominal pressures. The catheter was made of polyethylene tubing and was 1.19 mm in internal diameter. The abdomen was closed in two layers. Bilateral interpleural catheters were then inserted in the posterior axillary line at either the seventh or eighth intercostal space. The technique used for insertion is similar to that described by Stromskag et al. (1). Portex epidural catheters were inserted into the pleural space to a depth of 10 cm at the skin and sutured in place.

Airway pressure was measured through a side port in the endotracheal tube. Both airway pressure and intraabdominal pressure were measured with a Validyne MP45-14 differential pressure transducer. One milliliter of air was injected into the abdominal balloon catheter. The diaphragmatic wires were attached to a Grass high-impedance probe (model HIP511, Grass Instruments Co., Quincy, Mass.) and a ground wire was attached to subcutaneous tissue at the site of the femoral incision. The signals were then amplified, rectified, and averaged with a moving time averager with a 100% response time of 100 ms. Both raw and averaged EMG signals were recorded. The EMG activity of each hemidiaphragm was measured, but only one hemidiaphragm EMG could be recorded on paper at a time. A Hans Rudolph heated pneumotachograph (model 3700) was attached to the endotracheal tube for measurement of both inspiratory and expiratory flow and tidal volume. The experimental preparation is shown in Figure 1.

The following variables were measured continuously throughout the experiment: airway pressure, intraabdominal pressure, tidal volume, flow, and the raw and averaged EMG signals of one hemidiaphragm. After a stabilization period of 30 min, the dog's airway was occluded by clamping the endotracheal tube (Figure 1) at end expiration. The occlusion was maintained for three consecutive inspiratory efforts (Figure 2). The occlusion maneuver was performed to assess the contribution of the ipsilateral hemidiaphragm to total inspiratory effort (see subsequent text). The clamp was then released. After the occlusion maneuvers, either 0.5% bupivacaine or normal saline solution in a volume of 0.3 mL/kg body wt was injected through an interpleural catheter. The ipsilateral EMG was recorded. Occlusion maneuvers of the airway were repeated every 5 min for 30 min. The contralateral EMG was then measured, and baseline measurements for that hemidiaphragm were made as described earlier. The corresponding interpleural catheter was injected with either bupivacaine or saline solution. Occlusion maneuvers of the airway were again repeated every 5 min for 30 min. Interpleural bupivacaine was injected on nine occasions and normal saline solution on four occasions in an attempt to obtain a 2:1 distribution of active treatment versus placebo. Two dogs received bupivacaine bilaterally.

At the end of the experiment, the dog was killed with an intravenous injection of KCl. Bilateral thoracotomies were done to assess the location of the interpleural catheter and to determine the presence of lung trauma that may have occurred during the insertion of the catheter. The results were classified into three categories:

1. Complete loss of nerve conduction. This was indicated by complete loss of phasic EMG activity in the ipsilateral diaphragm.
2. Partial loss of nerve conduction. The EMG of the ipsilateral diaphragm decreased (but was not abolished), with no corresponding decrease in occlusion pressure.
3. No effect. No change in EMG or occlusion pressure or corresponding changes in both variables.

Results

In total, interpleural bupivacaine was injected on nine occasions and normal saline solution on four occasions. In one dog, an adequate EMG signal could not be obtained from the left hemidiaphragm because of electrocardiographic interference. Thus, only one side was injected in this animal. In five of nine experiments in which bupivacaine was injected, there was complete loss of EMG activity on the side of the

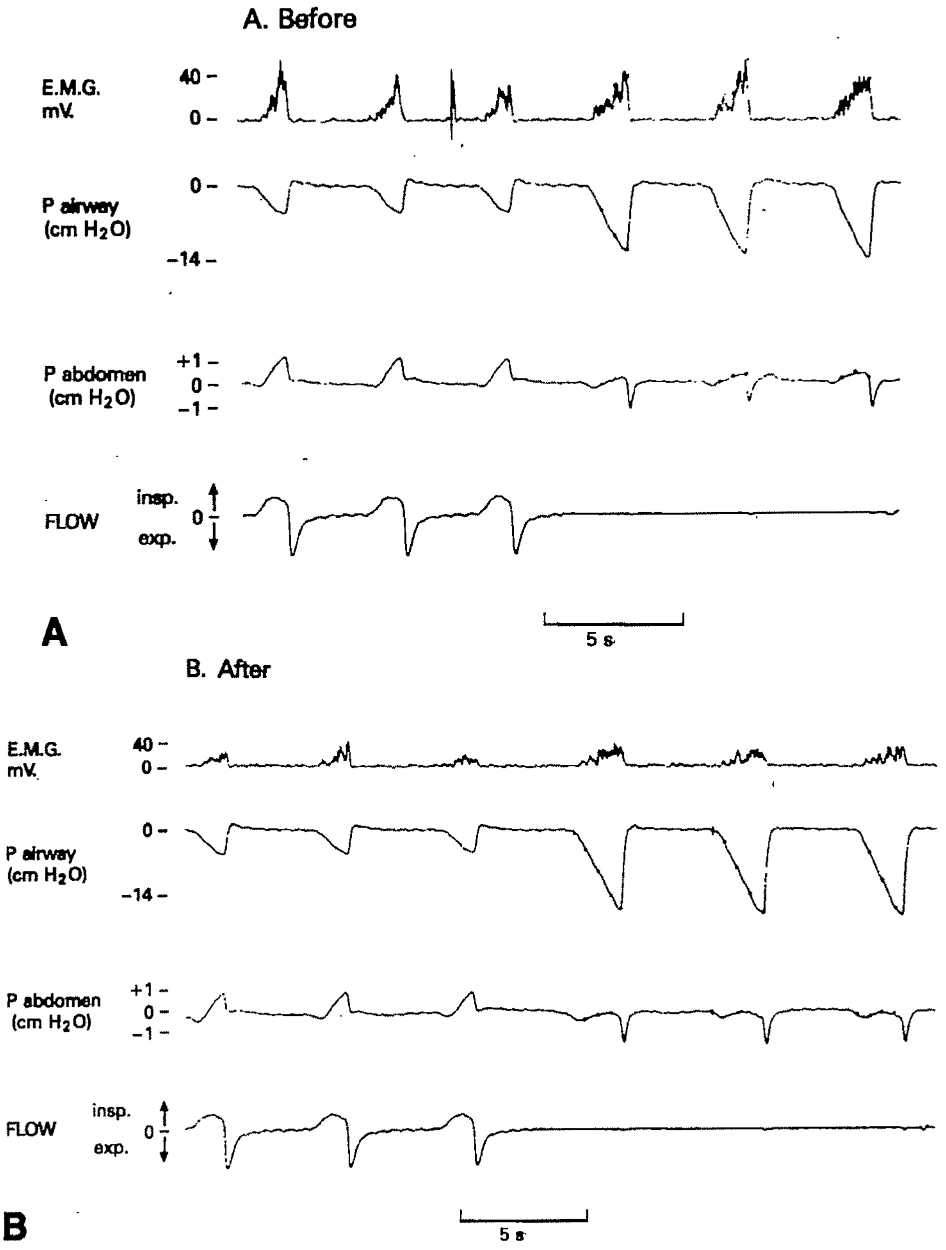

Figure 2. An example of a decrease in the amplitude of the diaphragmatic electromyographic (E.M.G.) signal: (**A**) before and (**B**) 30 min after injection of 0.5% bupivacaine. injection. In two of the experiments with bupivacaine, there was no visible change in EMG, and the inspiratory intraabdominal pressures remained positive. In the remaining two experiments with bupivacaine, there was a decrease in the intensity of EMG signal with no corresponding decrease in occlusion pressure. An example is shown in Figure 2.

The most striking observation was made in the two dogs that received bilateral interpleural injections of bupivacaine. These dogs developed paradoxical respirations with negative inspiratory intraabdominal pressures, as shown in Figure 3. In one dog there was a complete loss of EMG activity bilaterally; in the other dog paradoxical respiration occurred with loss of EMG in one hemidiaphragm and a diminished, although still present, EMG in the other hemidiaphragm. In the normal saline solution group, there was no change in the EMG and no change in inspiratory intraabdominal pressure.

At the conclusion of all of the experiments, the interpleural catheters were all located in the pleural space. The position of the catheter tip was variable,

with some located posteroapically and others more posterocaudally. There was no evidence of lung trauma in any dog.

Discussion

The pressure generated at the airway during occlusion at functional residual capacity is a reflection of the collective activity of all inspiratory muscles and is used as a measure of respiratory drive (12). The electrical activity recorded from the EMG wires is a reflection of activity in the sampled muscle. The latter may change, either because of local block of the motor fibers supplying that muscle (this is the response being sought) or because of global changes in respiratory drive responding to a change in level of anesthesia, temperature, etc. In the event that changes in measured EMG are related to changes in global drive, both EMG and occlusion pressure should change in the same direction and by roughly the same extent. Changes in EMG not matched by similar changes in occlusion pressure would indicate a selective action on the motor supply of the sampled muscle.

The results show that diaphragmatic dysfunction can result from interpleural injection of bupivacaine in the dog. The observation of paradoxical respirations with negative intraabdominal pressures provides unequivocal evidence of this. The negative intraabdominal pressure is produced by the continued inspiratory activity of the intercostals, resulting in a paradoxical upward, rather than the normal downward, displacement of the diaphragm. The volume of bupivacaine that was injected was small (0.3 mL/kg body wt) in an attempt to use the comparable volume used in humans (20 mL for a 70-kg subject). In addition, the dogs were kept supine during the experiment. No attempt was made to tip the animal one way or the other, to direct the local anesthetic toward the phrenic nerve.

The anesthetic used for the experiment may have affected the results obtained, in that halothane has negative inotropic properties on diaphragmatic muscle in both the dog and the rat (13,14). Halothane progressively decreases the transdiaphragmatic pressure generated by phrenic nerve stimulation in both animal models. This phenomenon appears to be caused by a negative inotropic action, as opposed to interference with neuromuscular transmission. Nevertheless, EMG activity is preserved, although diminished, at levels up to 2% inspired halothane concentration. Halothane may have decreased the baseline EMG measurements in the experiments, but the concentrations used (1% inspired) could not by themselves cause loss of EMG activity. Also, there was no evidence of diaphragmatic dysfunction during baseline measurements before injection of bupivacaine.

The EMG signal can be affected because of technical reasons, such as blood or fluid accumulation around the diaphragmatic wires. It was believed that this was unlikely to have caused the changes seen because of the lack of changes seen in the group that received interpleural normal saline solution and because the change in EMG activity was so closely related to the injection of bupivacaine.

Diaphragmatic dysfunction can be caused by laparotomy in both humans and dogs with noxious visceral stimulation (i.e., either by cholecystectomy or simply by applying traction to the gallbladder bed) (15,16). Care was taken during the surgical preparation to minimize any unnecessary visceral manipulation. At the end of surgical preparation, with the abdomen closed, all dogs were breathing in a normal manner, generating positive intraabdominal pressures during inspiration. Again, no animal had evidence of diaphragmatic dysfunction before interpleural injection.

Is the dog an appropriate model to use for this experiment? In both dogs and humans, the phrenic nerve follows a similar course through the thorax to the diaphragm. In both species, there is a layer of mediastinal pleura separating the phrenic nerve from the pleural space (17,18). In the dog, the phrenic nerve splits into three main branches (ventral, lateral, and dorsal) as it enters the diaphragm (17). The phrenic nerve in humans also splits into three branches: the anterior, anterolateral, and posterior branches. The posterior/dorsal branch supplies the crural portion of the diaphragm (18). The dog, like humans, has a connection between each phrenic nerve and the sympathetic nervous system at the celiac plexus. The periphery of the diaphragm receives sensory innervation from the last several intercostal nerves in both humans and dogs, but the phrenic nerve is the only motor nerve to the diaphragm. Although there are differences in the shape of the thoracic cavity between humans and dogs, phrenic nerve anatomy and diaphragmatic innervation are quite similar.

It is possible that if the phrenic nerve is blocked at the site where it divides into its three branches, one or two of its branches may be blocked, leaving the remaining branches intact. In this experiment, the diaphragmatic wires were placed only in the costal portion of the diaphragm. Thus, isolated paralysis of the crural portion may not have been detected. Theoretically, it is possible to block a portion of the diaphragm and obtain partial dysfunction of the diaphragm. It need not be an "all-or-none" phenomenon.

It is important to note that the diaphragm is not one muscle; rather, it consists of two distinct muscles; the costal and crural portions. Both have different motor innervation, fiber composition, and embryologic origins. The diaphragm has a complex mechanical arrangement, with the costal and crural portions of the diaphragm acting as if they were mechanically arranged, partly in parallel and partly in series at functional residual capacity and gradually moving into a purely mechanical series as lung volume increases (19). During quiet respiration, the crural portion shortens more than the costal and also shortens before the costal portion begins to contract.

De Troyer et al. (20) have demonstrated that under the proper circumstances, isolated contraction of the costal portion of the diaphragm without contraction of the crural portion may result in paradoxic respiration with negative intraabdominal pressures (20). This may have occurred in one of the dogs in which EMG activity was still present in one hemidiaphragm, but paradoxical respiration was observed.

Qualitative changes in the EMG were observed in two dogs. The significance of this observation is not known, but one might speculate that this is a manifestation of partial phrenic nerve blockade.

In conclusion, diaphragmatic dysfunction can occur in dogs after interpleural administration of 0.5% bupivacaine. The factors that predispose diaphragmatic dysfunction to occur in one animal as opposed to another are not known. The exact site of phrenic nerve blockade is also not known. One cannot directly extrapolate from this experiment to the use of interpleural analgesia in humans. However, it should be determined whether complication can occur in humans, and if so, what are its incidence and significance.

Departments of Anesthesiology, Pediatrics (Hematology), and Surgery, Sainte-Justine Hospital, and the University of Montreal, Montreal, Quebec, Canada

Desmopressin (DDAVP) has been reported to reduce bleeding in patients undergoing spinal fusion. To evaluate its efficacy in normal patients, 30 healthy young patients (ASA physical status I or II) undergoing spinal fusion for idiopathic scoliosis were randomly allocated to receive either 100 mL of physiologic saline solution (placebo group) or DDAVP (10 $\mu g/m^2$ of body surface area) (DDAVP group) in a prospective, double-blind trial. Intraoperative blood loss was measured by weighing sponges and suction drainage and postoperative bleeding by wound drainage. The amount of blood loss expressed as a percent of the estimated blood volume was similar in both groups during the intraoperative period (67.0% ± 28.8% [mean ± SD] placebo group vs 57.4% ± 26.5% DDAVP group), the postoperative period up to 24 h (32.5% ± 6.4% placebo group vs 31.1% ± 10.6% DDAVP group), and both periods (94.3% ± 29.4% placebo group vs 88.2% ± 30.7% DDAVP group). With the dose used in our study, we conclude that DDAVP does not reduce surgical bleeding in patients undergoing spinal fusion for idiopathic scoliosis.

(Anesth Analg 1992;75:405–10)

Surgery for scoliosis is a procedure associated with large blood loss, during which patients may lose their total estimated blood volume or more (1,2). Factors influencing bleeding are the extent of dissection; number of fused vertebrae; length of surgery; surgical technique used, including type of instrumentation, site, and size of bone graft and phase of operation in which it is obtained; and mean arterial blood pressure and pressure in the inferior vena cava (3,4). In patients with idiopathic scoliosis, hemostatic abnormalities may in some cases increase the bleeding problem. Despite a bleeding time that is usually within the normal range, half of these patients have abnormal platelets with a depressed aggregation in response to epinephrine and adenosine diphosphate (5). Furthermore, the collagen from patients with idiopathic scoliosis aggregates platelets only one-fourth as efficiently as the collagen from normal patients (6).

Desmopressin (DDAVP) is an analogue of the natural hormone vasopressin with an antidiuretic/pressor ratio that is approximately 2000- to 3000-fold greater than that of vasopressin. Substitution of D-arginine for L-arginine in position 8 results in a markedly diminished pressor activity, or V_1 effect, whereas deamination of cystein in position 1 allows for an increase in the antidiuretic, or V_2, effect and increases the length of action, with a half-life of 2.5–4.4 h (7,8). Through its V_2 effects, desmopressin also causes endothelial cells to release von Willebrand factor, tissue-type plasminogen activator, and certain prostaglandins. An increase in the release of von Willebrand factor, particularly the higher molecular-weight multimers, accounts for the hemostatic activity of DDAVP in patients with uremia, chronic liver disease, and certain types of von Willebrand's disease by promoting platelet adhesiveness to the vascular endothelium (9–12). Desmopressin has also been reported to minimize intraoperative blood loss in patients undergoing cardiac surgery with extracorporeal circulation, although the results have been variable, with some authors finding a decrease in bleeding, whereas others have found no beneficial effects (13–16).

Kobrinsky et al. (17) reported that a single dose of 10 $\mu g/m^2$ of body surface area of DDAVP adminis-

tered immediately after induction of anesthesia could reduce intraoperative bleeding by 30% in patients undergoing spinal fusion surgery with a normotensive anesthesia technique. However, firm conclusions with regard to patients with idiopathic scoliosis cannot be drawn from this study, because patients enrolled had either idiopathic scoliosis or scoliosis secondary to cerebral palsy or neuromuscular disorders. In spinal fusion surgery, the use of DDAVP can be hazardous because its V_2 effects may worsen the syndrome of inappropriate antidiuretic hormone secretion already present in that type of surgery (18–20). The aim of this study was to evaluate the efficacy of DDAVP in reducing blood loss in spinal fusion surgery for idiopathic scoliosis.

Methods

Thirty healthy (ASA physical status I or II) consecutive patients (28 female, 2 male) with idiopathic scoliosis scheduled for spinal fusion who met the inclusion criteria were randomly allocated (block randomization) to receive at the time of skin incision either 100 mL of physiologic saline solution (placebo group) or DDAVP (10 $\mu g/m^2$ body surface area) (maximal dose 20 μg) in the same amount of saline solution (DDAVP group) infused in 20 min. Blood volume was estimated at 60 mL/kg in the female subjects and at 65 mL/kg in the male subjects (21). If the patient was obese, body surface area and estimated blood volume were calculated by using the higher acceptable body weight for height (22). The design was double blind, and the surgeon, the anesthesiologist, and the investigator collecting the experimental data were all unaware of which solution was administered. Patients were not considered for inclusion in the study if a different surgical technique was used (i.e., the absence of wound drainage to allow postoperative bleeding measurement). Patients were also excluded if they had one of the following: history of a bleeding diathesis, ingestion of drugs known to interfere with hemostasis, abnormal bleeding time (>9 min), prolonged (>36 s) activated partial thromboplastin time, prolonged (>25 s) thrombin time, prolonged (>16 s) prothrombin time, or a low platelet count ($<150 \times 10^9$/L). This protocol was accepted by the ethics committee of our institution, and informed consent was obtained for each patient.

During surgery, patients were monitored with a cardioscope, a pulse oximeter, and an automated oscillometric blood pressure device. An arterial catheter was installed in the radial artery (20 gauge) and a central venous catheter introduced into the right internal jugular vein (16 gauge). Heart rate and blood pressure were recorded before the induction of anesthesia and every 5 min thereafter until the end of anesthesia. Central venous pressure, temperature, and urine output were recorded every hour during surgery. All patients were positioned on a Harrington frame. Anesthesia with normotension (65–85 mm Hg mean arterial pressure) was achieved with nitrous oxide, isoflurane, intravenous fentanyl (10–15 μg/kg), and pancuronium. Appropriate minute ventilation and fresh gas flows were calculated to maintain normocarbia with a coaxial circuit. Maintenance fluid requirements and third space losses were replaced with lactated Ringer's solution (6–10 $mL \cdot kg^{-1} \cdot h^{-1}$) to maintain the central venous pressure between 4 and 8 mm Hg. Surgical blood losses were compensated with lactated Ringer's solution up to 20%–30% of the estimated blood volume with a ratio of 3:1 and with packed red blood cells diluted in normal saline solution or banked autologous blood (eight patients in the placebo group and seven patients in the DDAVP group) for blood losses exceeding 20%–30% of the estimated blood volume. For patients with homologous blood transfusion, fresh-frozen plasma was administered after loss of 50%–100% of the estimated blood volume.

The skin was infiltrated with 20–250 mL of a solution of epinephrine 1:1,000,000, and all patients underwent a Cotrel-Dubousset technique executed by one of the two surgeons participating in the study. In brief, exposition of the bony elements was done from the upper vertebra to the lower vertebra chosen to be fused. After harvesting cortical and cancellous bone from the right iliac crest, hooks were inserted. Decortication of laminae, facet joints, and transverse processes was performed at every level, and rods were inserted with a derotation maneuver as indicated. A wake-up test was performed, and bone graft was packed at all levels to be fused. Wound drainage was inserted before closure.

Bleeding time was measured before surgery with a Simplate (Organon Teknika, Durham, N.C.). Blood samples were obtained for the measurement of hemostatic values before and 20 min after DDAVP administration by venipuncture (21-gauge needle) or from the central venous catheter (first 10 mL discarded) and sent to the laboratory in silicone-coated vacutainer tubes (Becton Dickinson, Rutherford, N.J.) containing 105 mM buffered citrate, for a final ratio of one part anticoagulant to nine parts of blood. After two consecutive centrifugations at 12,000*g* for 10 and 20 min, respectively (4°C), platelet-poor plasma was fast-frozen and kept at −70°C until used. Coagulation tests were done with a Fibrintimer 10 (Behring Diagnostics, Montreal, Canada). Prothrombin time, partial thromboplastin time, and thrombin time (Organon Teknika) were performed as recommended by the manufacturer. Factors V and VIII were measured in a one-stage assay. Von Willebrand factor was measured by quantitative immunoelectrophoresis (23). Euglobulin lysis time and fibrin plate lysis were measured as described previously (24,25). Hemostasis tests were considered abnormal if their results exceeded the mean plus two standard deviations of results obtained from 20 regular normal volunteer donors. Samples for the measurement of hemoglobin, hematocrit, and blood and urinary sodium and osmolality were taken before DDAVP administration and at 1, 8, 14, and 24 h after skin incision. Hemoglobin, hematocrit, and platelet counts were determined with Technicon H-1 (Tarrytown, N.Y.). Blood and urinary osmolality were determined by the freezing-point depression (Microosmometer, Advanced Instruments Inc., 3MO) and sodium levels in blood and urine were measured with an ion-specific electrode (ISE, Parallel American Monitor). Intraoperative blood loss was measured by weighing sponges and suction drainage, and postoperative bleeding by wound drainage (Snyder, Hemovac) during the next 24 h.

Data were analyzed for statistical significance with analysis of variance for repeated measures, followed by the Scheffé multiple-comparisons test, variance-covariance analysis, unpaired *t*-test, and χ^2 test with Yates' correction when appropriate. Statistical significance was determined at $P < 0.05$, and the number of patients was determined to detect a difference in blood loss of 30% with a β error of 0.2. Data are presented as mean ± SD.

Results

Only one patient could not participate in the study because of a prolonged bleeding time. The two groups were comparable for gender distribution, age, body surface area, minimal temperature, number of fused vertebrae, curve angle, length of surgery, preoperative bleeding time, and quantity of epinephrine used (Table 1). There were no obese patients in the placebo group compared with six in the DDAVP group. Heart rate and central venous pressure were not different between the two groups. The mean arterial pressure was lower in the DDAVP group than in the placebo group for up to 45 min, with the largest difference at 30 min (67.6 ± 9.3 vs 79.3 ± 7.4 mm Hg, respectively) and was comparable in both groups thereafter. All hematologic variables were in the normal ranges and similar in both groups before the intervention.

Desmopressin induced a significant increase in Factor VIII coagulant (+61.2% ± 68%; $P < 0.001$) and in von Willebrand factor (+44.4% ± 64.2%; $P < 0.005$). Both groups had a comparable decrease in their platelet count during surgery (Table 2). The increase in Factor VIII coagulant and in von Willebrand factor for the obese patients in the DDAVP group (+69.7% ± 64.2% and +46.3% ± 57.1%, respectively) was comparable to that observed for the nonobese patients in the same group (+55.0% ± 74.4% and +42.9% ± 73%, respectively).

The amount of blood loss as a percent of the estimated blood volume was similar in both groups for the intraoperative period (i.e., 67.0% ± 28.8% [placebo group] vs 57.4% ± 26.5% [DDAVP group]), the postoperative period up to 24 h (32.5% ± 6.4% [placebo group] vs 31.1% ± 10.6% [DDAVP group]), and both periods (94.3% ± 29.4% [placebo group] vs 88.2% ± 30.7% [DDAVP group]) (Table 3). The power of the study to detect a difference of 30% in blood losses between the two groups was close to 1 for each of these three values. The total amount of blood loss for the obese patients in the DDAVP group was similar to that of the nonobese patients in the same group (i.e., 97.7% ± 34.4% of estimated blood volume, or 3128 ± 1125 mL, for normal patients, compared with 75% ± 19% of estimated blood volume, or 2887 ± 791 mL, for the obese patients). The total amount of blood loss for patients operated on by one of the two surgeons was 93.6% ± 30.2% of estimated blood volume, or 3161 ± 1142 mL (10 patients in the DDAVP group and 13 in the placebo group), and 95.2% ± 36.0% of estimated blood volume, or 3056 ± 926 mL, for the other surgeon (five patients in the

DDAVP, desmopressin.
Mean ± SD; the two groups were comparable for all values.

DDAVP group and two in the placebo group). No patient in either group needed a second surgical procedure to control postoperative bleeding.

There was a significant difference in diuresis during the first 3 h of surgery ($P < 0.05$) and during the entire 24 h (30.9 ± 11.9 [placebo group] vs 22.9 ± 8.1 [DDAVP group]; $P < 0.05$) (Table 1). Variations of blood and urinary sodium and osmolality were similar in both groups. One patient in the DDAVP group had sodium <130 mEq/L 8 h after DDAVP, and 46% of all patients had serum osmolality <275 mOsm/kg H_2O at 24 h after skin incision (i.e., eight patients in the placebo group and six in the DDAVP group).

Discussion

In this study, we administered a single dose of DDAVP to patients with idiopathic scoliosis who had no known disorder of hemostasis and with normal preoperative coagulation tests. After DDAVP, both Factor VIII and von Willebrand factor increased significantly by 61.2% and 44.4%, respectively. However, the administration of DDAVP provided no real benefit, because it did not significantly reduce the total blood losses during the entire 24-h period; neither did DDAVP diminish intraoperative or postoperative blood transfusion requirements (Table 3).

It is surprising at first glance that bleeding was not decreased, considering the abnormalities of hemostasis often seen in patients with idiopathic scoliosis (5,6). An increase in von Willebrand factor by DDAVP should have improved hemostasis in these patients, because this factor mediates the adhesion of platelets to damaged endothelium (8). The absence of blood loss reduction by DDAVP may be explained by the fact that only patients without significant clinical bleeding disorders and with normal preoperative coagulation tests were enrolled in our study, thus possibly excluding patients who could have benefited most from a substance-enhancing hemostasis. However our patients represent the usual population undergoing surgery for idiopathic scoliosis, because the hemostatic abnormalities found in patients with idiopathic scoliosis seldom lead to a prolonged bleeding time or to clinical bleeding problems (6). This was well demonstrated during the course of our study when only one patient could not be enrolled because of abnormal preoperative coagulation tests. To date, most authors who administered DDAVP to reduce blood loss in patients without significant clinical bleeding disorders for uncomplicated surgery failed to demonstrate any beneficial effect (14–16). Our results differ from those of Kobrinsky et al. (17) who reported that DDAVP reduced the amount of intraoperative blood loss by 30% during scoliosis surgery; however, they studied a group of patients who had scoliosis of varying etiologies and found that DDAVP seemed more useful in patients with scoliosis secondary to neuromuscular disorders. There seems to be a difference in the reduction of blood loss by DDAVP between patients with idiopathic scoliosis and patients who have developed scoliosis because of an underlying neuromuscular pathology (17). Certain platelet anomalies have been reported in patients with Duchenne type muscular dystrophy, particularly a marked increase in the calcium and phosphorus content of platelets (26). It is possible that there is an abnormal bleeding process in the muscle tissue of these patients and that this particular type of bleeding may be helped by the use of DDAVP.

The following factors may account for the fact that DDAVP did not reduce bleeding in normal patients undergoing spinal fusion for idiopathic scoliosis. The epinephrine liberated during the surgical stress and administered subcutaneously before surgical incision might have caused an increase in von Willebrand factor in both groups, considerably reducing the beneficial effect of DDAVP (27). It is also possible that under general anesthesia or during surgery, or both, the release of Factor VIII and von Willebrand factor usually seen after the administration of DDAVP is incomplete or that there is an increased consumption of these factors during the surgical period. In this study, the increase in Factor VIII and von Willebrand factor (61% and 44%, respectively) after DDAVP was comparable to results described in patients who received a dose of 0.3 μg/kg of DDAVP during surgery under general anesthesia (50% and 35%, respectively) (28). However this increase is relatively modest compared with that usually observed either in normal patients or in patients with von Willebrand's disease who received the same dose of DDAVP (0.3 μg/kg) outside the surgical period, which is then 400% and 300% for Factor VIII and von Willebrand factor, respectively (12). Our DDAVP group included six obese patients versus none in the placebo group, and DDAVP dosage was established by using the body surface area determined with the higher acceptable weight for height and up to a maximal dose of 20 μg. It is possible that with this method, the dose of DDAVP administered in the obese patients was inferior to the optimal dose. However we do not think that this is the case for the following reasons: the increase in Factor VIII and von Willebrand factor for the obese patients in the DDAVP group was similar to that for the nonobese patients in the same group (i.e., 69.7% ± 64.2% and 46.3% ± 57.1%, respectively, for the obese patients compared with 55.0% ± 74.4% and 42.9% ± 73%, respectively, for the nonobese patients). Furthermore, the bleeding in the obese patients in the DDAVP group was not increased compared with that of the nonobese patients in the same group (i.e., 75% ± 19% of estimated blood volume, or 2887 ± 791 mL, in the obese patients compared with 97% ± 34% of estimated blood volume, or 3128 ± 1125 mL, in the nonobese patients). Certain side effects of DDAVP may have counterbalanced the otherwise beneficial rise in the release of von Willebrand factor. The vasodilating properties of DDAVP could have possibly increased the bleeding process, at least during the first hour after its administration (29,30). Also, the release of tissue-type plasminogen activator may have produced a fibrinolysis that we were unable to detect (8). Finally, the blood vessels in bone are noncollapsible structures that are supported by the bone lamellae and consequently will remain open when the bone is cut. This type of bleeding is particularly difficult to control and may not be readily influenced by substances that modify hemostasis.

The inability to reduce bleeding during the postoperative period could be due to the administration of a single dose of DDAVP, because in a normal individual the half-life of Factor VIII and von Willebrand factor after injection of DDAVP is 266 and 563 min, respectively (12). There is no evidence, however, that multiple doses would have helped to lower blood loss during the postoperative period, given the lack of response in the intraoperative period and the usual reduction in efficiency of DDAVP with increasing number of doses administered. Indeed, DDAVP does not produce an increase in synthesis of Factor VIII and von Willebrand factor but only releases existing stocks of these factors, which explains the rapid occurrence of tachyphylaxis (12).

Desmopressin is a potent vasodilator with a direct muscular effect that is partially modulated by constricting and dilating prostaglandins (29,30). In this study, the observed decrease in blood pressure was without consequence, because the maximal difference in mean blood pressure between the two groups was only 12 mm Hg. A decrease in diuresis due to DDAVP was evident for only a short period after its administration, because patients in the placebo group had a progressive reduction in diuresis, with mean values of <1 mL·kg^{-1}·h^{-1} after the third hour of surgery. There was no increase in the incidence of hypoosmolality caused by DDAVP, because the number of patients with a serum osmolality of <275 mOsm/kg H_2O at 24 h was comparable in both groups.

In conclusion, with the dose used in our study, DDAVP does not reduce surgical bleeding in patients without a known bleeding diathesis undergoing spinal fusion for idiopathic scoliosis.

Effect of Desmopressin Acetate on Hindlimb Perfusion Pressure in Rats: What Is the Mechanism?

Jonathan S. Jahr, MD, Ronald H. Holton, MS, and Chang-Jian Feng, MD
Department of Anesthesiology, Tulane University School of Medicine, New Orleans, Louisiana

Desmopressin acetate (DDAVP) is a synthetic analogue of vasopressin used to promote hemostasis and reduce postoperative blood loss. Desmopressin acetate can cause hypotension in humans. Our study evaluated the hemodynamics of rapid administration of DDAVP into the isolated hindlimb in live rats and assessed this response after pretreatment with various antagonists. Thirty male Sprague-Dawley rats (350–450 g) were given intraperitoneal pentobarbital anesthesia (50 mg/kg). Perfusion was set at a rate that gave a control mean hindlimb perfusion pressure (HPP) of 100–120 mm Hg. Rats were assigned to five groups ($n = 5$, each group), with each rat serving as its own control. As a control, saline solution (in volumes equivalent to those used for the antagonists) was injected into the hindlimb preparation before the agonist injections. Each group received both the clinical preparation of DDAVP (i.e., with preservative) and a laboratory preparation of DDAVP in doses of 0.3–3 ng. Group 1 was tested before and after injection of saline solution control; group 2, before and after propranolol (0.5 mg/kg); group 3, before and after meclofenamate (1.5 mg/kg), a cyclooxygenase inhibitor; group 4, before and after nitroarginine (5 mg/kg), an inhibitor of nitric oxide synthesis; and group 5, before and after atropine sulfate (1 mg/kg). Chlorobutanol (25–75 μg), the preservative in the clinical preparation of DDAVP, was tested for changes in HPP in five rats similarly prepared. Systemic mean arterial pressure remained constant during the study. The HPP decreased with increasing doses of the clinical preparation of DDAVP, compared with saline solution controls, whereas no change occurred with the laboratory preparation of DDAVP. There were no changes after meclofenamate, chlorobutanol, or propranolol with either clinical or laboratory DDAVP; however, an additional significant decrease in HPP occurred with both atropine and nitroarginine ($P < 0.001$) for only the clinical preparation of DDAVP. We conclude that the clinical preparation of DDAVP, but not the laboratory preparation of DDAVP, causes significant dose-dependent vasodilation of the hindlimb vascular bed in the live male rat. The mechanism of this vasodilation is a direct action on vascular smooth muscle (nitric oxide studies) or receptor activity (atropine studies) or V_2-receptor agonism.

(Anesth Analg 1992;75:411–5)

Desmopressin acetate (1-desamino-8-D-arginine vasopressin) (DDAVP) is a synthetic analogue of vasopressin. It is used clinically in the treatment of diabetes insipidus (1), hemostasis and postoperative bleeding in patients with platelet dysfunction (2,3), and platelet dysfunction associated with cardiopulmonary bypass (4).

Desmopressin acetate also produces hypotension (5–8). We recently described 16 patients undergoing cardiac surgical procedures who were prospectively randomized into two groups to study the hemodynamic and possible histamine-releasing effects of DDAVP administration after cardiopulmonary bypass. We concluded that DDAVP at 0.3 μg/kg is a potent vasodilator when administered intravenously and that histamine is not involved (8).

Previous work examined possible roles of mediators or receptors that may be involved in DDAVP-induced vasodilation. Bichet et al. (5) hypothesized that stimulation of extrarenal V_2-like receptors by DDAVP results in hypotension. The clinical preparation of DDAVP decreases arterial blood pressure in the anesthetized rat (Jahr J, Kuchta K, Texidor M, Stevens K; personal communication) and relaxes isolated segments of aorta and pulmonary artery (9). Johns (9) has shown, using both in vitro rabbit and rat aortic root strips, that neither V_1- or V_2-antagonists nor H_1- or H_2-blockers have any mediating effects on DDAVP-induced vasodilation, although cyclooxygenase inhibitors such as indomethacin may potentiate this vasodilation. No in vivo studies exist that

confirm mediator involvement in the vasodilation or hypotensive actions of DDAVP.

In the present study, responses to the laboratory and clinical preparations of DDAVP were investigated in the hindlimb vascular bed of the anesthetized rat under constant flow conditions so that changes in hindlimb perfusion pressure directly reflected changes in vascular resistance, testing a variety of antagonists and a nitric oxide inhibitor, as well as the preservative in the clinical preparation of DDAVP.

Methods

After Animal Care Committee approval, 30 male Sprague-Dawley rats (350–450 g) were given intraperitoneal pentobarbital anesthesia (50 mg/kg). Supplemental doses of anesthetic were given as needed to maintain a uniform level of anesthesia. The animals were mechanically ventilated with room air enriched with oxygen delivered by a cannula into the trachea. Arterial blood gas samples were obtained periodically; ventilation and oxygenation were maintained at normal values. Polyethylene tubing for venous access was placed by cutdown into the jugular vein to allow administration of the volume required to maintain homeostasis. One of the axillary arteries was dissected and cannulated to monitor systemic mean arterial pressure. A cutdown and cannulation of the right carotid artery provided the source of arterial blood, which was fed to a Harvard peristaltic pump for perfusing blood to the hindlimb vascular bed. The inferior abdominal aorta was cannulated immediately above the bifurcation with polyethylene tubing through which the output of the Harvard pump was infused. Heparin (1000 U/kg) was administered intravenously before perfusion. The hindlimb perfusion pressure and systemic mean arterial pressure were constantly monitored and recorded on a Grass model 7 polygraph. Perfusion was set at a rate that gave a control mean hindlimb perfusion pressure of 100–120 mm Hg. The animal's temperature was maintained at 37°C with a heating pad and monitored by rectal thermometer.

The clinical preparation of DDAVP (Rorer Pharmaceuticals, Fort Washington, Pa.) was supplied as a 4-μg/mL solution in 0.9% saline solution (pH adjusted to 4.0), containing chlorobutanol (1,1,1-trichloro-2-methyl-2-propanol) as preservative. The laboratory preparation of DDAVP (Peninsula Laboratories, Belmont, Calif.) was dissolved similarly in 0.9% saline solution, with the pH adjusted to 4.0 with HCl. Atropine sulfate, propranolol, and meclofenamate (Sigma Chemical Co., St. Louis, Mo.) were dissolved in 0.9% saline solution; these solutions were stored at −20°C and used within 2 wk.

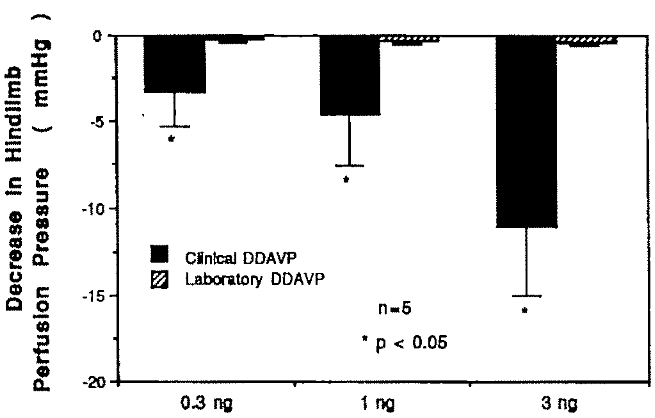

Figure 1. Comparison of laboratory and clinical preparations of DDAVP in the hindlimb vascular bed of the male rat.

N^{ω}-nitro-L-arginine (Aldrich, Milwaukee, Wis.) was dissolved at 10 mg/mL in 0.05 N HCl in 0.9% saline solution with sonication immediately before use. As a control, saline solution (in volumes equivalent to those used for the agonists) was injected into the hindlimb preparation before the agonist injections. The experiment with the antagonist was not performed until the hindlimb preparation was stable throughout the experiment. Responses to the laboratory preparation of DDAVP (0.3–3 ng) and the clinical preparation of DDAVP (0.3–3 ng) were first obtained in each rat. Then, 10 min after return to baseline, rapid administration into the perfusion circuit was performed in four different groups, respectively: meclofenamate (1.5 mg/kg IV), propranolol (0.5 mg/kg IV), atropine (1 mg/kg IV), or N^{ω}-nitro-L-arginine (nitroarginine) (5 mg/kg IV). Systemic mean arterial pressure was monitored for stability, and hindlimb perfusion pressure was recorded. As the hindlimb perfusion pressure is isolated, the systemic mean arterial pressure should remain constant in a normal, healthy laboratory rat preparation. If a rat did not maintain this hemodynamic stability, it was removed from the study. Statistical comparisons were made by using the *t*-test, with a P value ≤0.05 considered significant.

Results

All rat preparations remained stable, with no changes in systemic mean arterial pressure. Rapid administration of the clinical preparation of DDAVP into the perfusion circuit elicited dose-dependent decreases in hindlimb perfusion pressure, compared with saline solution controls ($P < 0.05$) (Figure 1). Decreases in hindlimb perfusion pressure ranged from 3 to 11 mm Hg; however, administration of the laboratory preparation of DDAVP did not cause a significant

decrease in hindlimb perfusion pressure (Figure 1). The responses to both the laboratory preparation and the clinical preparation of DDAVP were not modified by propranolol (Figure 2), or meclofenamate (Figure 3); however, an additional significant decrease in hindlimb perfusion pressure with both atropine and nitroarginine was noted ($P < 0.001$) for the clinical preparation of DDAVP only (Figures 4 and 5). Chlorobutanol caused no change in hindlimb perfusion pressure.

Discussion

Salzman et al. (4) reported that patients undergoing various open-heart procedures had reduced perioperative blood loss when DDAVP was administered prophylactically. Desmopressin acetate is now used in some patients undergoing cardiopulmonary bypass, because this tends to degranulate platelets and to decrease their function (10).

Desmopressin acetate has few adverse effects (5). Most frequently noted is mild skin vasodilation, observed as facial flushing (6). This may be due to systemic release of prostacyclin (6). Desmopressin acetate is also known to produce hypotension (5–8). In our clinical study, rapid intravenous infusion of DDAVP after adult cardiopulmonary bypass revealed that DDAVP is a potent vasodilator and can cause significant hypotension (7). Further, in our clinical study, 16 patients undergoing cardiac surgical procedures were prospectively randomized into two groups to study the hemodynamic and histamine-releasing effects of DDAVP administration after cardiopulmonary bypass. We concluded that DDAVP at 0.3 μg/kg is a potent vasodilator when administered intravenously and that histamine is not involved (8).

Other mediators or receptors that may be involved in the DDAVP-induced vasodilation have been examined. Bichet et al. (5) reported no alteration in arterial blood pressure in patients with congenital diabetes insipidus who are congenitally devoid of V_1- and V_2-receptors. In contrast, in patients with central nephrogenic diabetes insipidus with intact V_1- and V_2-receptors, DDAVP administration lowered arterial blood pressure. Bichet et al. (5) hypothesized that stimulation of extrarenal V_2-like receptors by DDAVP results in hypotension. Recent studies have shown that DDAVP decreases arterial blood pressure in the anesthetized rat (Jahr J, Kuchta K, Texidor M, Stevens K; personal communication) and relaxes isolated segments of the aorta and pulmonary artery (9). Johns (9) has shown, using both in vitro rabbit and rat aortic root strips, that neither V_1- or V_2-antagonists nor H_1- or H_2-blockers have any modulating effects on DDAVP-induced vasodilation with either endothelium-intact or denuded vessels. The relaxation was partially dependent on intact endothelium and was potentiated by indomethacin, an inhibitor of cyclooxygenase (9). Chlorobutanol had no vasoactive effects (9). Unfortunately, Johns' (9) in vitro model represents capacitance and not resistance vessels, which may not be an appropriate model for testing vasodilation. No in vivo studies exist that confirm mediator involvement in DDAVP vasodilation.

The prophylactic or therapeutic administration of DDAVP in complicated cardiac surgery has been demonstrated to decrease blood loss perioperatively (4). However, DDAVP is not effective in decreasing blood loss in pediatric or adult patients undergoing uncomplicated cardiac surgery (10,11). Increased risk of early graft closure in patients undergoing coronary artery bypass grafting after DDAVP administration has also been reported (12), although no complications of this type were reported by Hackmann et al. (13). Current debate exists, therefore, over both the safety and efficacy of DDAVP in decreasing blood loss after cardiac surgery (14,15). If DDAVP is used, caution should be exercised after DDAVP administration owing to its potent vasodilator properties (8).

These results demonstrate that the clinical preparation of DDAVP has vasodilator activity in the hindlimb vascular bed of the rat and that responses to this preparation are not dependent on activation of β-adrenergic receptors or release of vasodilator prostaglandins. The experiments with nitroarginine, an inhibitor of nitric oxide synthesis from L-arginine, and atropine suggest that our DDAVP-induced vasodilator responses were dependent in part on the release of nitric oxide or a related nitroso compound derived from L-arginine or muscarinic receptor blockade, or both. The clinical preparation of DDAVP contains chlorobutanol as preservative, but the latter did not have vasoactivity. The two preparations were similar in terms of vehicle (0.9% saline solution), concentration, and pH.

Our results conflict with those of Johns (9), who found DDAVP-induced relaxation to be partially dependent on cyclooxygenase inhibitors. Johns did not assess muscarinic blockers or nitroarginine. We found no effect from meclofenamate. The difference may be in the experimental preparations, in vitro compared with in vivo, and the fact that the aortic strips that Johns investigated were not resistance vessels. Pulmonary vessels, although they are resistance vessels, often have differing drug response effects from systemic vessels. Only the clinical preparation of DDAVP, not the chlorobutanol nor the laboratory preparation of DDAVP, caused vasodilation. The additional vasodilation effects of atropine and nitroarginine suggest both a muscarinic receptor effect (vasoconstriction) and a direct vascular smooth muscle mechanism. A recent editorial review confirms the vasodilatory effects of nitroarginine, a nitric oxide congener: there is speculation that nitroarginine may even be an endothelium-derived relaxing factor (16). Another possibility for the vasodilation is direct V_2-receptor stimulation by the clinical preparation of DDAVP; however, we did not assess this. It is puzzling that the clinical preparation of DDAVP caused vasodilation when both the laboratory preparation and the chlorobutanol did not. Perhaps this difference may be explained by the concentrated DDAVP preparation or by impurities; however, from these data, one should not dismiss the results of the clinical preparation.

We conclude that the clinical preparation of DDAVP causes significant dose-dependent vasodilation of the hindlimb vascular bed of the live male rat, whereas the laboratory preparation of DDAVP does not. The vasodilatory mechanism is not β_2-adrenergic receptor agonism or blockade of the arachidonic acid cascade. Atropine and nitroarginine may augment the vasodilation, suggesting direct action on vascular smooth muscle, muscarinic receptor activity, or possibly, V_2-receptor agonism. The preservative of the clinical preparation of DDAVP, chlorobutanol, appears to have no vasodilatory effect. Therefore, the differences encountered may be a result of the DDAVP concentrate.

Effects of Atipamezole, an α_2-Adrenoceptor Antagonist, on the Anesthesia Induced by Barbiturates and Medetomidine

Timo Kauppila, MD, Erkki Jyväsjärvi, DD, and Antti Pertovaara, MD

Department of Physiology, University of Helsinki, Helsinki, Finland

We studied the effects of atipamezole, an α_2-adrenoceptor antagonist, on hypnosis induced by medetomidine, an α_2-adrenoceptor agonist (1 mg/kg IP), and pentobarbital (40 mg/kg IP) by testing the righting reflex in the rat. The duration of antinociception was assessed with repeated pinch tests. Medetomidine-induced hypnosis and antinociception were inhibited by atipamezole at doses >0.1 mg/kg. Atipamezole restored the righting reflex at a dose ratio that was 1:10 or more to that of medetomidine used to induce hypnosis. Subcutaneous atipamezole (1.5 mg/kg) increased the duration of hypnosis induced by pentobarbital (40 mg/kg) and pentobarbital + medetomidine (0.3 mg/kg). Hypnosis induced by methohexital (60 mg/kg IP) was also prolonged by atipamezole. The capacity of atipamezole to reverse the effects of medetomidine is also reduced in the presence of barbiturates. Thus, atipamezole should be used only at low doses to reverse a combination anesthesia induced by barbiturates and medetomidine.

(Anesth Analg 1992;75:416–20)

Atipamezole, an α_2-adrenoceptor antagonist, is more specific in binding to α_2-receptors than are the older α_2-antagonists yohimbine or idazoxan (1). However, atipamezole also interferes with serotonergic (2) and α_1-adrenergic systems (1). It reverses medetomidine-induced sedation (1), analgesia (3), and *d*-medetomidine-induced hypnosis (4) in the rat. Because humans tolerate atipamezole well (5), it has been suggested for clinical use as an antianesthetic drug (6).

In animal experiments, *d*-medetomidine enhances the effects of inhaled anesthetics (7,8) and opiates (9). Yet, *d*-medetomidine reduces opiate-induced side effects during anesthesia (10,11). *d*-Medetomidine may also be used as an anesthetic in its own right rather than as an adjunctive or supplemental drug (7). A racemic (1:1) mixture of active *d*- and inactive *l*-medetomidine used for premedication in dental surgery (12) or in human experimental pain studies (13) reduces the apprehension related to painful procedures. Moreover, *d*-medetomidine, used as premedication in minor gynecologic surgery, reduces the amount of thiopental needed for the induction of anesthesia (14).

Our study determined the relative dose of atipamezole that antagonizes the hypnotic and antinociceptive effects of medetomidine. We also studied the effects of atipamezole on methohexital-, pentobarbital-, and pentobarbital + medetomidine-induced anesthesia.

Methods

Animals

Naive male Han-Wistar rats (aged 5–6 mo, weight 410–540 g, six per cage, light 12 h-dark 12 h, lights on 6 AM to 6 PM, humidity 35%–50%, food ad libitum) were used. In the experiments presented here, the volume of injections of saline solution or atipamezole was 0.5 mL/kg, unless otherwise indicated. During the experiments, the body temperature of the rats was kept constant with heating lamps. The experiments were performed between noon and midnight.

Testing Procedures

The experimental procedures used were approved by the Ethical Committee of Animal Research of the University of Helsinki and the Provincial Government of Uusimaa, Finland.

This study was supported by the Academy of Finland and the Research and Science Foundation of Farmos-Group, Ltd, Turku, Finland.

Accepted for publication April 10, 1992.

The animals were tested for two variables: hypnosis by means of the righting reflex and analgesia by means of a tail-pinch test. Hypnosis was determined as a state in which a rat could be placed on its back after induction of anesthesia without righting itself. The duration of this state was referred to as the duration of hypnosis (4). The duration of analgesia during anesthesia was determined with the modified pinch test, in which a standard hemostatic clamp was applied to the tail. The latency to the biting or licking of the clamp was measured (3). First, eight control rats underwent tail-pinch testing 20 min after injection of saline solution to determine the 95% confidence level for comparison with the subsequent drug-induced analgesia results. On the basis of these tests, the clamp was removed after 60 s if no response was observed. The tests were performed 20 min and once every hour after the first anesthetic injection for 5–8 h.

Experiment I

In this experiment, five groups of six animals were studied to investigate the dose and the site-related effect of atipamezole to antagonize both the hypnotic and analgesic effect of medetomidine. All five groups received medetomidine (1 mg/kg IP [1 mL/kg] [Domitor, Farmos-Group Ltd., Turku, Finland]), and each of the five groups received one of the following: subcutaneous saline solution or atipamezole (0.03, 0.1, or 0.3 mg/kg SC or 0.1 mg/kg IP) (adjusted to a volume of 0.5 mL/kg) 5 min after the injection of medetomidine. The duration of hypnosis and analgesia was then determined as described earlier.

Experiment II

To determine the effect of atipamezole pretreatment on medetomidine-induced anesthesia (as done previously with *d*-medetomidine [4]), three groups of six rats were used. Fifteen minutes before the administration of medetomidine (1.0 mg/kg IP), each of the three groups was injected intraperitoneally with atipamezole (0.1 or 0.3 mg/kg) or saline solution. The duration of hypnosis and analgesia was then determined as described earlier.

Experiment III

In the first part of this experiment, three groups of six rats were first injected subcutaneously with pentobarbital (40 mg/kg [0.67 mL/kg]) and then with atipamezole (0.3 and 1.5 mg/kg) (5,6) or saline solution (0.5 mL/kg) 5 min later. In the second part, two groups of six rats were used. Both groups simultaneously received pentobarbital (40 mg/kg IP) and medetomidine (0.3 mg/kg [1 mL/kg]) in the abdominal subcutis. To avoid possible direct chemical interaction between the injected anesthetics, medetomidine was injected subcutaneously. The groups received saline solution (0.5 mL/kg) or atipamezole (1.5 mg/kg) in the dorsal subcutis 5–10 min after injections of pentobarbital. The duration of hypnosis and analgesia were determined as described earlier.

Experiment IV

To study the effects of atipamezole on the anesthesia induced by a fast-acting barbiturate, methohexital (60 mg/kg IP [2 mL/kg]) was administered to 16 rats. Eight of the rats received atipamezole (1.5 mg/kg SC [0.3 mL/kg]), and the other eight received saline solution (0.3 mL/kg SC) 5 min after methohexital injections. The duration of hypnosis was determined as in the previous experiments.

Statistical Analysis

To compare the duration of hypnosis or response latencies to pinch at a given time point, Kruskal-Wallis analysis of variance was applied. To compare the effects of the different treatments with the effects of saline solution treatment, the two-tailed Mann-Whitney U-test was applied; $P \leq 0.05$ represented a statistically significant difference.

Results

Experiment I

The effects of medetomidine (1 mg/kg IP) on the righting reflex and on the reaction to pinch were completely antagonized if the dose of atipamezole was ≥0.1 mg/kg SC (atipamezole was administered 5 min after medetomidine) (Figures 1 and 2). However, when atipamezole was administered intraperitoneally, the reversal of the effect of medetomidine on the reaction to pinch was not as complete as with subcutaneous administration of atipamezole (Figure 2).

Although the medetomidine-induced loss of righting reflex was reversed at the dose of 0.1 mg/kg of atipamezole, the rats were sedated and immobile for the first 3–4 h of the 5-h follow-up time. Atipamezole (0.03 mg/kg) did not decrease the duration of the medetomidine-induced loss of righting significantly, but it seemed to prolong the onset of hypnosis: 10 min after medetomidine injection, three of six rats had not lost their righting reflex, whereas all rats in the medetomidine + saline solution-treated group

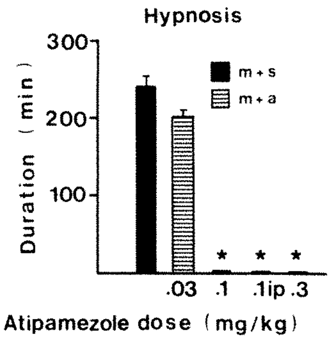

Figure 1. Effects of different doses of atipamezole on the duration of hypnosis induced by medetomidine (1 mg/kg IP). The duration of hypnosis was determined as the duration of the loss of the righting reflex. Atipamezole was injected subcutaneously 5 min after medetomidine. *Bars* show the means and *brackets* the SEM of the treatment groups. The differences between the groups are statistically significant ($P < 0.001$, f = 4, Kruskal-Wallis). *Statistically significant difference from the medetomidine + saline solution-treated rats ($P < 0.05$, Mann-Whitney). s, Saline solution; m, medetomidine; a, atipamezole.

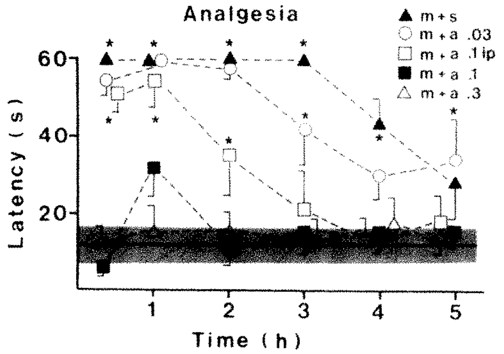

Figure 2. Effects of different doses of atipamezole on analgesia induced by medetomidine (1 mg/kg IP). The analgesic effect was determined as an increase in the biting latency to a noxious tail pinch. Atipamezole was injected subcutaneously 5 min after medetomidine. *Symbols* show the means and *brackets* the SEM in the treatment groups. A *horizontal line* shows the mean and a *shaded area* shows the ±SEM of the biting latencies in the saline solution-treated rats ($n = 8$). The groups differ from each other from 20 min to 4 h statistically significantly ($P < 0.05$, f = 5, Kruskal-Wallis). *Statistically significant difference from the response latencies in the saline solution-treated rats ($P < 0.05$, Mann-Whitney). s, Saline solution; m, medetomidine; a, atipamezole.

had lost this reflex. For the three atipamezole-treated rats, the medetomidine-induced loss of the righting reflex took 30–50 min to occur.

After the medetomidine + saline solution injections, the righting reflex of two of six of the rats was restored for a few seconds after the tail pinch at 20 min and 1 h. A motor response to the tail pinch was seen in medetomidine + saline solution-treated rats: at least a phrenic twitch was present in all animals.

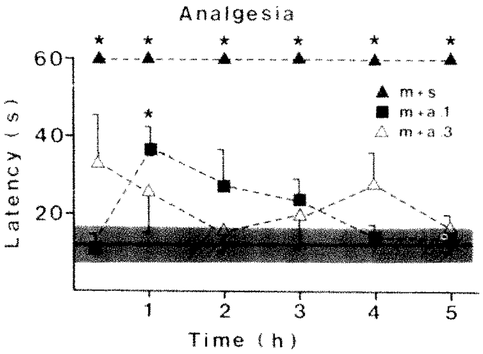

Figure 3. Effects of different doses of atipamezole on analgesia induced by medetomidine (1 mg/kg IP). Atipamezole was injected intraperitoneally 15 min before medetomidine. The groups differ from each other statistically significantly for the entire follow-up period ($P < 0.001$, f = 3, Kruskal-Wallis); symbols as in Figure 2.

Experiment II

When injected 15 min before medetomidine, doses of 0.1 and 0.3 mg/kg IP of atipamezole completely prevented the medetomidine-induced loss of righting reflex (duration 188 ± 16 min [mean ± SE]). The medetomidine-induced increase in the response time to pinching was also inhibited by atipamezole after the first hour of follow-up (Figure 3).

After the medetomidine + saline (both intraperitoneal) injections, the righting reflex of two of six of the rats was restored for a few seconds after the tail pinch at 20 min and 1 h. The phrenic motor response to the tail pinch was seen in all medetomidine + saline solution-treated rats.

Experiment III

Atipamezole (1.5 mg/kg SC) increased the duration of the pentobarbital-induced loss of the righting reflex and the pentobarbital-induced prolongation of the response latencies to the pinch (Figures 4 and 5). With a smaller dose of atipamezole (0.3 mg/kg), only the effect of pentobarbital on the pinch-response latencies was prolonged (Figure 5).

The temporary pinch-induced recovery of the righting reflex was also seen in one of the six pentobarbital-treated rats. The phrenic motor response to the tail pinch was also seen in all barbiturate-treated rats.

If medetomidine (0.3 mg/kg) was combined with pentobarbital, atipamezole (1.5 mg/kg) prolonged their effect on the righting reflex when compared with the pentobarbital + medetomidine + saline solution-treated rats (Figure 4). The effect on the pinch-induced reaction was not prolonged (Figure 5).

After treatments with pentobarbital + medetomidine + saline solution or pentobarbital + medetomi-

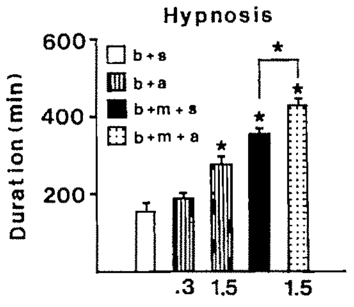

Figure 4. Effects of different doses of atipamezole on the duration of hypnosis induced by pentobarbital (40 mg/kg IP) or pentobarbital + medetomidine (0.3 mg/kg SC). Atipamezole was injected subcutaneously 5–10 min after the anesthetics. b, Pentobarbital. *Statistically significant difference from pentobarbital + saline solution-treated rats ($P < 0.05$, Mann-Whitney); other symbols as in Figure 1. The groups differ from each other statistically significantly ($P < 0.001$, f = 4, Kruskal-Wallis).

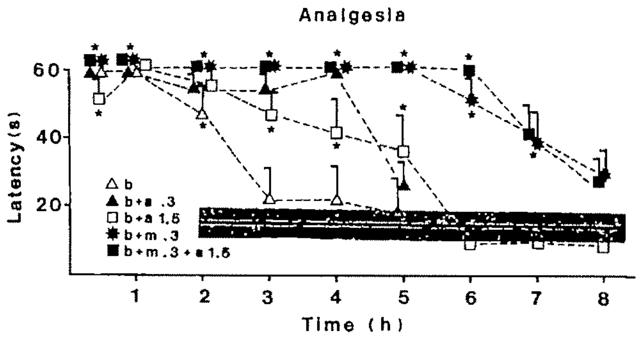

Figure 5. Effects of different doses of atipamezole on analgesia induced by pentobarbital (40 mg/kg IP) or pentobarbital + medetomidine (dose of medetomidine 0.3 mg/kg SC). Atipamezole was injected subcutaneously 5–10 min after the anesthetics. b, Pentobarbital; symbols as in Figure 2. The groups differ from each other from 20 min to 7 h statistically significantly ($P < 0.05$, f = 5, Kruskal-Wallis).

dine + atipamezole, no tail pinch-evoked motor responses were observed for the first 2 h.

Experiment IV

Methohexital-induced loss of righting reflex was also prolonged with atipamezole (1.5 mg/kg SC; 33.5 ± 6.0 min [mean ± SE]; $n = 8$) compared with the duration of metohexital + saline solution-induced hypnosis (19.6 ± 2.8 min; $n = 8$; U = 13, $P \leq 0.05$, Mann-Whitney).

Discussion

The medetomidine-induced hypnosis (i.e., the loss of righting reflex) lasted 3–4 h. This is in line with previous observations of the hypnotic effect of *d*-medetomidine: 0.5 mg/kg produced hypnosis for 3 h and 1 mg/kg for 4.5 h (4,15). When medetomidine (0.3 mg/kg) was combined with pentobarbital (40 mg/kg), the analgesic effect was more profound for the first 2 h (i.e., no motor responses could be observed), and the hypnosis lasted longer than with medetomidine or pentobarbital alone. This is consistent with previous observations in which medetomidine enhanced the effects of thiopental (14) and halothane (7,8).

Medetomidine-induced anesthesia alone is not sufficient for adequate surgical analgesia and hypnosis at the dose range used. Although response latencies to the tail pinch increased after medetomidine treatment, pinching of the tail restored the righting reflex in two of six of the rats. Furthermore, the pinch-evoked phrenic motor response was always seen if only medetomidine was used. It is not always possible to distinguish between antinociception and other reasons for delayed or missing responses to noxious stimuli by means of behavioral pain tests. Yet, there are some electrophysiologic studies that suggest that medetomidine at the dose range used in this study (16) and in *d*-medetomidine (17) produce antinociception in rats. Medetomidine (12,13) also reduces pain-evoked affective reactions. Thus, the delayed responses to the tail pinch observed in our experiments suggested that medetomidine caused mild analgesia.

The dose of atipamezole needed to restore the righting reflex during medetomidine-induced anesthesia was smaller than reported earlier. After administration of atipamezole at a dose ratio of 1:10 to that of medetomidine, the righting reflex was present regardless of whether it was injected 5 min after or 15 min before the administration of medetomidine. This corresponds to a dose ratio of 5:1 between *d*-medetomidine and atipamezole. In the study of Doze et al. (4), however, the dose ratio between *d*-medetomidine and atipamezole at which the righting reflex was not lost was 1:2 when atipamezole was injected intraperitoneally 15 min before *d*-medetomidine. Because the hypnotic effect of 1 mg/kg of medetomidine should be equal to 0.5 mg/kg of *d*-medetomidine (4,14), the difference cannot be explained by a different potency of *d*-medetomidine in the preparations used. Furthermore, Virtanen et al. (1) reported that medetomidine-induced (1 mg/kg) absence of spontaneous locomotor activity was partly inhibited by a dose of 0.3 mg/kg of atipamezole injected 30 min before medetomidine. Thus, atipamezole seems to be less effective against *d*-medetomidine alone than against the same amount of *d*-medetomidine in a racemic mixture. This may be due to an interaction between *l*-medetomidine and *d*-medetomidine or *l*-medetomidine and atipamezole.

Administration of atipamezole at a dose of 0.1 mg/kg SC reduced the medetomidine-induced increase of the response latency to tail pinching. The same dose of atipamezole injected intraperitoneally did not reverse this medetomidine-induced effect as clearly unless it was administered 15 min before medetomidine. It may be that the two solutions interact if they are injected close to each other in the same tissue within a short time. Moreover, intraperitoneal administration of atipamezole may be less effective than subcutaneous atipamezole because of high first-pass metabolism in the liver (6).

Atipamezole increased the duration of barbiturate-induced hypnosis and analgesia. This effect is opposite to that of yohimbine (18). Yohimbine shortened the duration of anesthesia that was induced with pentobarbital and xylazine, another α_2-adrenoceptor agonist (19). However, atipamezole failed to antagonize hypnosis and analgesia induced by pentobarbital and medetomidine. The mechanism of this action is unclear. Of note, atipamezole mimics the effects of pertussis toxin on *d*-medetomidine- and pentobarbital-induced anesthesia (15). Pertussis toxin, which inhibits the intracellular messenger functions of inhibitory G-proteins, decreases the hypnotic effect of *d*-medetomidine and potentiates the hypnotic effect of pentobarbital (15). Thus, atipamezole may somehow interfere with the functions of the inhibitory G-proteins.

d-Medetomidine + thiopental-induced anesthesia is already in use in clinical trials (14). Use of atipamezole in the reversal of *d*-medetomidine-induced effects in humans is undergoing clinical trials (20). In healthy human volunteers, 1.5 mg/kg of atipamezole (i.e., the highest dose of atipamezole used in this study) may cause side effects; however, these were not considered to be very unpleasant by the study subjects (6): sweating or coldness of the limbs, restlessness, tremor, increased salivation, light-headedness, or facial flush. Because atipamezole is well tolerated, it can perhaps be used as an antianesthetic drug in humans (20). In humans, the dose ratio of atipamezole to *d*-medetomidine in reversal of sedation is 40:1 (20). Because high doses of atipamezole may be needed for reversal of the effects of *d*-medetomidine in humans, the interaction between barbiturates and atipamezole should be considered when clinical experiments are planned. According to present data, high doses of atipamezole may even potentiate the effects of anesthesia induced by a combination of a barbiturate and medetomidine.

The authors thank Dr. Ernst Mecke for his technical assistance.

Blood Flow and Tissue Oxygen Pressures of Liver and Pancreas in Rats: Effects of Volatile Anesthetics and of Hemorrhage

Brigitte Vollmar, MD, Peter F. Conzen, MD, Thomas Kerner, MD, Helmut Habazettl, MD, Martin Vierl, MD, Helmut Waldner, MD, and Klaus Peter, MD

Institutes of Surgical Research and of Anesthesiology, and the Department of Surgery, Innenstadt, Ludwig-Maximilians-University, Munich, Germany

The object of this investigation was to compare the effects of volatile anesthetics and of hemorrhage at comparable arterial blood pressures on splanchnic blood flow (radioactive microspheres) and tissue oxygenation of the liver and pancreas (surface Po_2 [Pso_2] electrodes). In contrast to earlier studies, we did not use identical minimum alveolar anesthetic concentration multiples as a reference to compare volatile anesthetics; rather, we used the splanchnic perfusion pressure. Under general anesthesia (intravenous chloralose) and controlled ventilation, 12 Sprague-Dawley rats underwent laparotomy to allow access to abdominal organs. Mean arterial pressure was decreased from 84 ± 3 mm Hg (mean ± SEM) at control to 50 mm Hg by 1.0 ± 0.1 vol% halothane, 2.2 ± 0.2 vol% enflurane, and 2.3 ± 0.1 vol% isoflurane in a randomized sequence. For hemorrhagic hypotension, blood was withdrawn gradually until a mean arterial pressure of 50 mm Hg was attained. Volatile anesthetics and hemorrhage reduced cardiac output, and hepatic arterial, portal venous, and total hepatic blood flows by comparable degrees. Mean hepatic Pso_2 decreased significantly from 30.7 ± 2.6 mm Hg at control to 17.4 ± 2 and 17.5 ± 2 mm Hg during enflurane and isoflurane (each $P < 0.05$) anesthesia, respectively. The decrease to 11.5 ± 2.5 mm Hg was more pronounced during halothane anesthesia. Hemorrhagic hypotension was associated with the lowest hepatic Pso_2 (3.4 ± 1.3 mm Hg) and the highest number of hypoxic (0–5 mm Hg 86%) and anoxic Pso_2 values (0 mm Hg 46%). Pancreatic blood flow and oxygenation remained unchanged from control during halothane and enflurane administration, whereas isoflurane increased both variables. Hemorrhagic hypotension slightly reduced pancreatic flow (−8%) but significantly decreased Pso_2 from 58 ± 5 mm Hg at control to 36 ± 3 mm Hg, with 7% of all measured values in the hypoxic range. Thus, volatile anesthetics preserved pancreatic but not hepatic blood flow and tissue oxygenation in this rat model. Despite comparable effects on perfusion, the Pso_2 of the liver and pancreas was the least during hemorrhagic hypotension compared to that with the anesthetics. Because the volative anesthetic-induced hypotension has such a different effect on splanchnic tissue oxygenation compared with hemorrhagic-induced hypotension, the authors conclude that the method of inducing hypotension may have different effects on oxygenation of various tissues.

(Anesth Analg 1992;75:421–30)

General anesthesia interferes with central and peripheral control of the circulation and is often associated with decreases in arterial blood pressure and cardiac output. Volatile anesthetics decrease splanchnic blood flow (1–4) and deteriorate hepatic tissue oxygenation (5,6). When the minimum alveolar anesthetic concentration (MAC) principle was applied to investigate "equipotent" concentrations of anesthetics, isoflurane had the least effect on both systemic hemodynamics and splanchnic oxygen supply, whereas halothane affected these variables the most, with enflurane intermediate (2–4,6,7).

For deliberate hypotension, volatile anesthetics can be administered to decrease arterial blood pressure to a desired level. There is, however, little information concerning the differences among clinically used halogenated anesthetics with respect to splanchnic perfusion at reduced arterial blood pressures. Knowledge of the differential effects of these anesthetics would be of relevance not only in patients with preexisting organ dysfunction, but would also

add to the general understanding of hepatocellular damage during inhaled anesthesia (8,9).

During all types of major surgery, splanchnic oxygen supply can be endangered by sudden blood loss. Hemorrhage curtails splanchnic perfusion (10–13) and influences oxygenation of the liver and other splanchnic organs in an unknown manner. This study was designed to evaluate the effects of the halogenated anesthetics in current clinical use and of hemorrhagic hypotension on the splanchnic circulation by measuring perfusion and tissue oxygen pressures on the surfaces of the liver and pancreas at identical levels of mean arterial blood pressure.

Methods

Animals and Experimental Preparation

After approval by the local animal care committee, experiments were performed in 12 male Sprague-Dawley rats (317 ± 15 g body wt [mean ± SD]). The animals were anesthetized with chloral hydrate (40 mg/100 g body wt) intraperitoneally. Sufficient anesthetic depth was achieved throughout the experiments by intravenous infusion of α-chloralose ($2\ \mathrm{mg \cdot 100\ g^{-1} \cdot h^{-1}}$). This anesthetic regimen was chosen because it had provided stable hemodynamic conditions in earlier experiments (14) as well as in control animals over several hours. After tracheotomy, controlled ventilation with oxygen in air was provided by a small-animal ventilator through the tracheal tube. The fraction of inspired oxygen ($\mathrm{FIO_2}$) was adjusted to maintain $\mathrm{PaO_2}$ at 110–120 mm Hg. At a rate of 50–55 breaths/min, tidal volume was set to maintain $\mathrm{PaCO_2}$ at 35 mm Hg.

The animals were placed on a heating pad to maintain rectal temperature at 37°C. Polyethylene tubing was inserted into the right femoral artery for determination of arterial blood pressure and for blood gas analyses. An intravenous catheter inserted into the superior vena cava through the right external jugular vein was used for intravenous infusion of fluids and drugs. Isotonic electrolyte solution was infused at a rate of $2.5\ \mathrm{mL \cdot kg^{-1} \cdot h^{-1}}$. A polyethylene catheter was inserted into the left ventricle through the right common carotid artery. Correct position of this catheter was verified by pressure recording. Another polyethylene catheter was inserted into the tail artery for withdrawal of reference samples during microsphere injections.

Surgical Procedure

The duodenal loop segment was gently exposed together with the intramesenterically located pancreas by median upper laparotomy and placed on a Plexiglas stage. Exposed-tissue temperature was controlled by a servo feedback heating device integrated into the Plexiglas stage. The laparotomy also provided liver access. Hepatic and pancreatic surfaces were covered by a Teflon membrane to prevent drying.

Measurement of Cardiac Output and Regional Blood Flow

Blood flow to splanchnic organs and cardiac output were determined by means of radioactive microspheres (15) with the reference sample technique previously described in detail (14). We used standard carbonized microspheres with a mean diameter of 15 μm (3M Company, St. Paul, Minn.). The microspheres were suspended in hydroxyethyl starch (MW 40,000) to slow sedimentation. For each blood flow determination 120,000–150,000 microspheres suspended in 0.3 mL of hydroxyethyl starch were injected over 20 s through the left ventricular catheter, which was subsequently flushed with 0.4 mL of saline solution. An arterial reference sample was withdrawn at a rate of 0.63 mL/min. Withdrawal was started 10 s before microsphere injection and continued for 40 s thereafter (16). The rats were killed after the last microsphere injection by intravenous KCl, and the organs were removed, weighed, and placed in counting vials.

Radioactivity was determined in the following organs: liver, pancreas, stomach, small and large intestine, spleen, and right and left kidney. The number of microspheres injected was determined by subtraction of residual activity in the injection syringe from its initial value. Radioactivity of reference and organ samples was measured in a 1024-channel multiple region-of-interest gamma counter with a 3-in. crystal (model 5650, Packard Instruments, Downers Grove, Ill.). The data were corrected for background and crossover activity with a specially designed software package (17). The number of microspheres trapped and blood flow were calculated for each sample. The relatively high number of microspheres injected ensured that all probes contained a minimum of 400 spheres. Portal venous blood flow was estimated as the sum of blood flow to stomach, pancreas, small and large intestine, and spleen (18). Preportal resistance was calculated as the quotient of mean arterial blood pressure to portal vein pressure difference and total preportal flow, assuming a portal venous pressure of 10 mm Hg (19). Cardiac output was calculated from the total number of microspheres injected. Animals with nonuniform distribution of microspheres manifested by differences between left and right kidney blood flow of >10% were excluded from study.

Determination of Hepatic and Pancreatic Surface Oxygen Tension

The method used here to determine oxygen pressure fields on liver and pancreas has been described in detail elsewhere (20,21) and has proved useful in a variety of studies (6,22–24). In brief, the measuring device consists of a Clark-type electrode incorporating eight thin platinum cathodes and one Ag/AgCl anode. At a constant polarization voltage of −700 mV, a single platinum wire (diameter 15 μm) registers a reduction current linearly dependent on the partial pressure of oxygen (Po_2). The radius of the oxygen-sensitive surface area of the wires depends on the thickness of the membrane used and is 20–25 μm with a membrane 25 μm thick. Electrodes were calibrated in physiologic saline solutions equilibrated with pure nitrogen and 5% and 10% oxygen in nitrogen, before and after each measurement. Reduction current was found to be linear within this range.

We also examined potential interference by the volatile anesthetics with electrode signals by equilibrating calibration media with different concentrations of the anesthetics (0–2 vol%). No impact on electrode signals was detected with isoflurane and enflurane, whereas halothane was reduced by the electrode, leading to an increased reduction current, as reported elsewhere (25). This increase was independent of the oxygen concentration in the gas, but depended linearly on the halothane concentration; 0.5 vol% halothane increased electrode readings by 3 mm Hg, 1 vol% by 6 mm Hg, and 1.5 vol% by 9 mm Hg. Correction of the data obtained during application of halothane was not performed, because tissue concentrations of halothane were not measured.

Reduction current signals from each of the eight channels were amplified, digitized, and processed with a PDP 11/23 computer (Digital Equipment Corporation, Maynard, Mass.). Histograms to describe the distribution of hepatic and pancreatic surface Po_2 (Pso_2) were constructed using Pso_2-width classes of 5 mm Hg. At each experimental step, a total of 100–120 individual oxygen pressure measurements was obtained at 12–15 different electrode locations on both the hepatic and pancreatic surfaces. The distribution of the Pso_2 values reflects average tissue oxygenation, giving the net result of nutritive blood flow, microcirculatory blood flow distribution, and tissue oxygen consumption (26). Snug contact of the electrodes with organ surfaces was verified by suffusion with 100% nitrogen or 100% oxygen. This procedure excluded diffusion of room air into the space between electrode and tissue, as well as resorption of oxygen from the ambient air by the superficially located vessels and subsequent detection by the measuring devices.

Experimental Protocol

Each protocol included a control period in which only the intravenous anesthetic was administered as well as four experimental steps with mean arterial blood pressure (MAP) decreased to 50 mm Hg by halothane, enflurane, isoflurane, or withdrawal of blood. The control recording and hypotension by volatile anesthetics were strictly randomized. When an experiment was started with hypotension by an anesthetic, MAP was adjusted to 50 mm Hg immediately after the surgical preparation had been accomplished, and measurements were started after 30 min of stable hypotension. Recordings of hemodynamics and arterial blood gas variables were obtained and hepatic and pancreatic tissue Pso_2 was measured. Hemodynamic and arterial blood gas measurements were then repeated and followed by injection of radioactive microspheres. A period of 45 min without a volatile anesthetic in the inspired gas followed. The MAP was then lowered by the next anesthetic. Control recordings were performed while no volatile anesthetic was given for another 30 min. Animals were excluded from study if after withdrawal of an anesthetic, arterial blood pressure and heart rate did not reach baseline values within a range of ±5%. Inspired concentrations of halogenated anesthetics were measured continuously (EMMA, Engström, Sweden).

The final step of each experiment was hypotension by hemorrhage, because control experiments had shown that retransfusion of blood often did not restore control values of hemodynamics and tissue Pso_2. For hemorrhagic hypotension, arterial blood was slowly withdrawn over 10 min to lower MAP to 50 mm Hg. Before the start of measurements, the animals were allowed to stabilize for at least 30 min.

Statistical Analysis

Results of hemodynamic and blood gas variables are expressed as mean ± standard error of the mean (SEM). Statistical analysis was performed with Friedman's ranked analysis of variance followed by Wilcoxon and Wilcox multiple comparisons.

The Pso_2 histograms were analyzed by their mean values as well as by the frequency of measurements in the lowest Pso_2 class (0–5 mm Hg) and by electrode readings not different from 0 mm Hg. These measur-

ing points are the most relevant to assessment of critically oxygenated tissue sites. Therefore, the total number of measurements in these classes was analyzed by χ^2 test. A P value <0.05 was considered statistically significant.

Results

Changes of systemic hemodynamic variables, arterial blood gases, and hemoglobin concentrations are summarized in Table 1. Splanchnic blood flow and distribution of cardiac output are given in Tables 2 and 3, respectively. Values of hepatic and pancreatic Pso$_2$ measurements are presented in Table 4 and in Figures 1 and 2.

Systemic Hemodynamic Variables

Control MAP was 84 ± 3 mm Hg. Decreases in MAP to 50 mm Hg required inspiratory concentrations of 1.0 ± 0.1 vol% halothane, 2.2 ± 0.2 vol% enflurane, and 2.3 ± 0.1 vol% isoflurane, respectively. Control heart rate (387 ± 7 beats/min) decreased significantly by 12% during halothane and enflurane anesthesia and by 10% during isoflurane anesthesia. Cardiac output decreased during halothane and enflurane

anesthesia by approximately 25% and to a lesser extent during isoflurane anesthesia (−19%). The better preservation of cardiac output during isoflurane anesthesia was largely due to a more pronounced decrease in systemic vascular resistance (−30%) compared with halothane and enflurane (−25%) anesthesia. Control left ventricular stroke volume was 0.22 ± 0.03 mL. Hypotension induced by either of the volatile anesthetics significantly reduced stroke volume by a comparable degree (−15%).

For hemorrhagic hypotension to MAP 50 mm Hg, 5.1 ± 0.7 mL of blood (i.e., 21% ± 3%) of the estimated circulating blood volume had to be withdrawn. Hemorrhagic hypotension decreased hemoglobin concentration (−22%). Heart rate significantly increased to 409 ± 8 beats/min, and cardiac output decreased by 27%. Thus, stroke volume significantly decreased by 32% to 0.15 ± 0.02 mL/min. Systemic vascular resistance decreased by 21%. Arterial blood gases, pHa, and bicarbonate remained in the control range throughout the experiments.

Splanchnic Blood Flow

During control administration, the liver was supplied by 7.5% ± 1% of cardiac output via the hepatic artery and by 23.7% ± 1.7% of cardiac output via the portal vein (Table 3). Hypotension by volatile anesthetics and hemorrhage decreased total hepatic blood flow by decreases in both arterial and portal venous inflow. Hepatic arterial blood flow decreased comparably by 47%, 46%, and 53% with halothane, enflurane, and isoflurane, respectively, and slightly less due to hemorrhage (−32%). Portal venous flow decreased to a comparable extent independently of the anesthetic used to produce the hypotension. Percent of cardiac output distributed to the liver decreased with volatile anesthetics but was unchanged from control during hemorrhagic hypotension. Within the preportal bed, except for the pancreatic gland, all organs followed the behavior of portal flow: blood flow decreased, but the fraction of cardiac output distributed to these organs remained essentially unchanged.

Pancreatic blood flow was slightly reduced during halothane and hemorrhagic hypotension. Enflurane and isoflurane increased pancreatic blood flow compared with control (+12%, NS; +27%, $P < 0.05$). The fraction of cardiac output received by the pancreas was slightly >1% during control and halothane administration and increased significantly to 1.58% and 1.38% during enflurane and isoflurane administration, respectively. Hemorrhagic hypotension increased this fraction slightly to 1.2%.

Left and right renal blood flow values in each

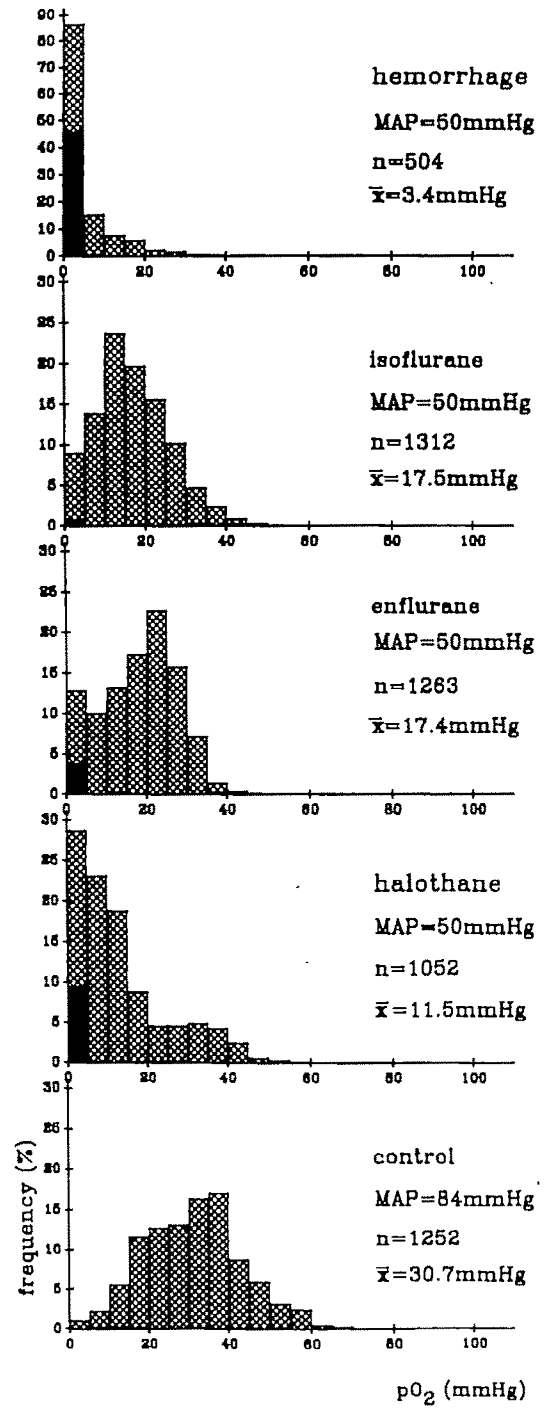

Figure 1. Summary hepatic Pso$_2$ distribution curves. The following experimental steps are given: control (MAP 84 ± 3 mm Hg); hypotension by halothane, enflurane, isoflurane, and hemorrhage (MAP 50 mm Hg). A significant leftward shift of the distribution curves (i.e., to lower mean values) and an increased number of low Pso$_2$ values were observed during hypotension. These changes were most pronounced during hemorrhagic hypotension, less during isoflurane and enflurane. *Solid bars*, relative numbers of measuring sites not detectably different from 0 mm Hg; *n*, total number of single measurements of each experimental condition; x̄, mean value of the summary histograms.

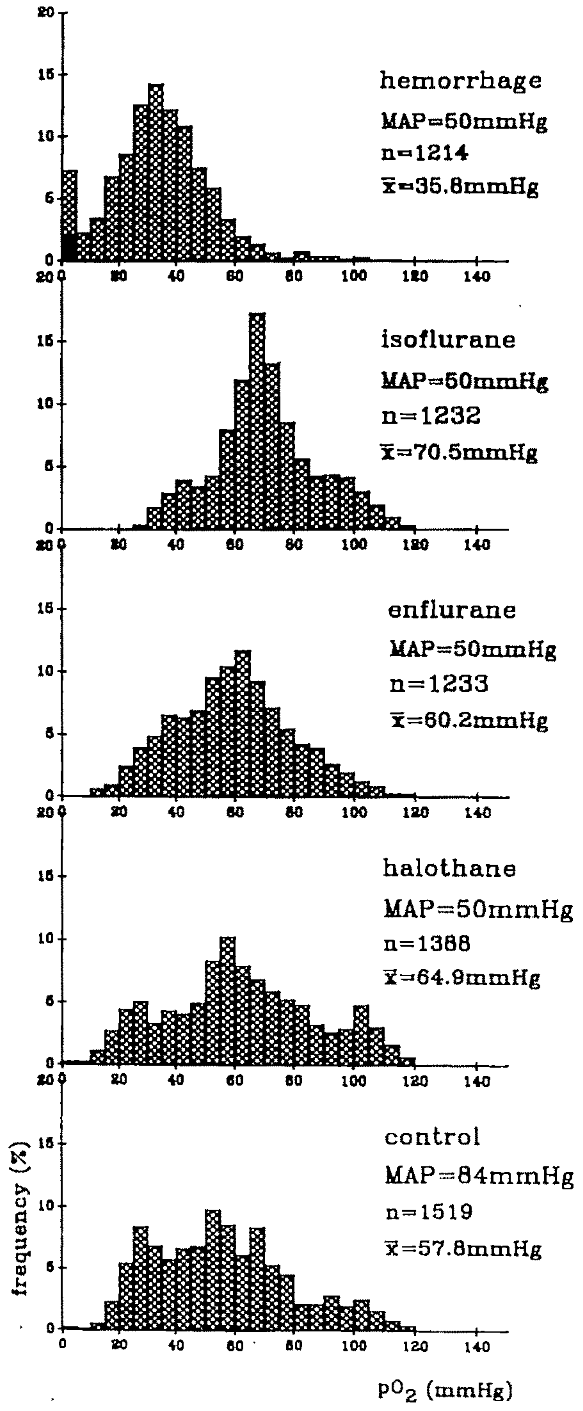

Figure 2. Summary pancreatic Pso$_2$ distribution curves. The control situation (MAP 84 ± 3 mm Hg) and the experiments with hypotension by halothane, enflurane, isoflurane, and hemorrhage (MAP 50 mm Hg) are given. No major changes of shape and mean value were detected during control and hypotension by any of the volatile anesthetics. Hemorrhage caused a leftward shift of the distribution curve and a significant increase of low Pso$_2$ values on the pancreas. *Solid bars* indicate measurements not detectably different from 0 mm Hg; *n*, total number of single measurements of each experimental condition; x̄, mean value of the summary histograms.

individual animal did not differ by >10%, indicating a homogeneous distribution of microspheres in the circulating blood.

Hepatic and Pancreatic Tissue Oxygenation

Hepatic Pso_2 histograms at control had a mean value of 31 ± 3 mm Hg, with 1% of measuring sites in the hypoxic range (0–5 mm Hg) and no readings of 0 mm Hg. During all hypotensive periods, a leftward shift of the summary histogram (i.e., to a smaller mean value) was detected (Figure 1). Despite comparable decreases in blood flow, there were marked differences in hepatic tissue Pso_2 among the volatile anesthetics and hemorrhagic hypotension. During isoflurane and enflurane anesthesia, hepatic Pso_2 decreased significantly by approximately 43%, to 17.4 and 17.5 mm Hg, respectively. Halothane caused a more pronounced leftward shift of the summary Pso_2 histogram, with the mean value reduced to 11.5 mm Hg (significantly less than enflurane and isoflurane). The frequency of Pso_2 recordings in the lowest histogram class (0–5 mm Hg) and Pso_2 recordings of 0 mm Hg amounted to 29% and 9% during halothane, and hence was significantly increased compared with enflurane (13%, 4%) and isoflurane (9%, 2%) (Table 4).

By far the lowest hepatic Pso_2 values were obtained during hemorrhage. The average Pso_2 (3.4 ± 1.3 mm Hg) was significantly different from Pso_2 values obtained during control and volatile anesthetics. Moreover, the frequency of Pso_2 values in the hypoxic range (0–5 mm Hg: 86%) was highest and significantly different from control and hypotension with volatile anesthetics (Table 4). Forty-six percent of measuring sites were not detectably different from 0 mm Hg.

The mean value of pancreatic Pso_2 was 57.8 ± 5.3 mm Hg at control, with no values in the hypoxic range (Figure 2). Administration of volatile anesthetics caused no significant changes. Mean values even increased during halothane, enflurane, and isoflurane anesthesia. The average pancreatic Pso_2 during hemorrhagic hypotension was 36 ± 3 mm Hg and hence significantly decreased from all other steps. Seven percent of the measurements were in the hypoxic Pso_2 class, and 2% were not detectably different from 0 mm Hg.

Discussion

We determined splanchnic blood flow and oxygenation of pancreatic and hepatic tissues during decreases in MAP to identical levels induced by volatile anesthetics and hemorrhage, respectively. Hypotension by anesthetics versus hypotension by hemorrhage decreased total hepatic blood flow to a comparable extent, whereas pancreatic flow was maintained. Hepatic tissue oxygen pressures decreased comparably with enflurane and isoflurane, but the decrease was more pronounced with halothane. Pancreatic oxygen pressures were slightly increased by the volatile anesthetics. Despite a comparable impact on organ perfusion, hemorrhagic hypotension impaired hepatic oxygenation considerably more than the volatile anesthetics and also decreased pancreatic oxygen pressures.

Experiments were performed in acutely instrumented and mechanically ventilated rats during constant background anesthesia. This was done to more closely reproduce the clinical situation in which volatile anesthetics are used as a tool to adjust anesthetic depth to varying intraoperative requirements or to control arterial blood pressure, or both. Earlier studies in animals have compared the effects of volatile anesthetics on the splanchnic circulation on the basis of their MAC values (3,4,6,27). The principle of MAC values implies equipotent cerebral concentrations, but disregards differing hemodynamic impact of the anesthetics. Thus, it appears difficult to differentiate the specific effects of the anesthetics on the splanchnic circulation from secondary consequences due to unspecific cardiocirculatory depression. In this study, we therefore compared anesthetic effects on the splanchnic vascular bed at the same arterial blood pressures.

The use of an anesthetized preparation reduced stress-induced disturbances of hemodynamic variables during sampling of control values. A further advantage was that the well-described negative effects on splanchnic circulation caused by onset of artificial ventilation were excluded. Controlled ventilation was also enabled not only during application of the volatile anesthetics, but also during the control period, thus avoiding the sequelae of alveolar hypoventilation by volatile anesthetics (i.e., hypoxemia and hypercapnia).

Certainly, the results of this study were not solely due to the effects of the volatile anesthetics or of hemorrhagic hypotension, because our anesthesia included separate drugs given for induction and maintenance of anesthesia (α-chloralose). As chloralose has minimal effects on gastrointestinal blood flow in small animals (28), we assumed that the effects of chloralose were small. This is supported by systemic hemodynamic and regional blood flow values similar to those obtained in conscious rats (16,29,30). Further, our anesthetic regimen was identical in all animals, and our experimental sequence—except for hemorrhage—was strictly randomized, thus minimizing influences of either baseline anesthesia or time on the results.

The intravenous anesthetic undoubtedly reduced the MAC values of the volatile anesthetics. The degree of reduction should be comparable, because chloralose was infused at an unchanged rate throughout the experiments, providing constant depth of background anesthesia. The inspired concentrations of the anesthetics probably closely resembled their end-expiratory concentrations, because each step was started with a high initial concentration of the anesthetic to achieve short equilibration periods. Accordingly, concentrations necessary to decrease MAP to 50 mm Hg would correspond to approximately 0.8 MAC halothane, 1.0 MAC enflurane, and 1.6 MAC isoflurane for unpremedicated rats (31). The differing MAC multiples applied in this study explain the apparent discrepancy with results of earlier studies in which isoflurane was found to preserve splanchnic flow better than equianesthetic concentrations of halothane or enflurane (4,6).

The technique of measuring surface tissue oxygen pressures by multichannel Clark-type electrodes has proved useful in a variety of studies (5,6,23,24). The measuring device permits atraumatic measurement of local tissue oxygenation. The hemispheric catchment area of a single wire of the electrode produces an averaged oxygen tension measurement from a tissue volume including several parenchymal cells and intravascular and interstitial space. The results of these Pso_2 measurements reflect local tissue oxygenation, giving the net result of oxygen delivery, microcirculatory blood flow distribution, and oxygen demand of the tissue. The Pso_2 measurements on organ surfaces do not necessarily reflect oxygen tensions in deeper layers of tissue. Because neither a hepatic nor pancreatic transmural oxygen gradient has been previously described, Pso_2 measurements can be assumed to describe whole-organ oxygenation.

The Pso_2 recordings not detectably different from 0 mm Hg do not necessarily indicate that intracellular Po_2 or cellular oxygen availability is in fact zero because of the poor resolution of the device in this range; however, we stress that these low values must be taken into consideration when evaluating the quality of tissue oxygenation. Statistical analysis was therefore performed not only with average Pso_2 values, but also with Pso_2 values in the lowest histogram class (0–5 mm Hg) and with values not detectably different from 0 mm Hg.

Hepatic Blood Flow and Oxygenation

In accordance with data on splanchnic blood flow of conscious rats (16,29,30), 76% of total hepatic blood flow in our study was provided by portal venous inflow (176 ± 12 $mL \cdot min^{-1} \cdot 100\ g^{-1}$) and 24% by the hepatic artery (54 ± 5 $mL \cdot min^{-1} \cdot 100\ g^{-1}$). Tissue oxygenation not only depends on the total amount of oxygen delivered, but also on local metabolic demands and microcirculatory blood flow distribution. The combination of these factors now yielded average tissue oxygen pressures of 31 mm Hg at control conditions. These data are in general agreement with results from the literature, although obtained in different animal species (i.e., piglets [32,33], pigs [5,6]) and under varying anesthetic protocols.

Comparison of the volatile anesthetics revealed that there were no profound differences with respect to blood flow and hepatic oxygenation. Total hepatic blood flow values with the highest flow during isoflurane anesthesia and the lowest during halothane anesthesia reflect the vasodilatory properties of these substances and agree with earlier investigations (4,19), although the differences did not reach statistical significance.

In contrast, despite comparable portal venous and hepatic arterial blood flow values, distinct differences with regard to hepatic tissue Pso_2 values were observed when we compared hypotension due to anesthetics versus hemorrhage. Hemorrhagic hypotension led to a dramatic decrease in tissue Pso_2. A high percentage of tissue sites measured below 5 mm Hg indicated tissue hypoxia (20). In contrast, the volatile anesthetics only mildly affected tissue Pso_2. Marked differences in organ oxygen consumption during hemorrhagic hypotension versus identical hypotension by volatile anesthetics would account for this discrepancy. Current evidence suggests no reduction of oxygen consumption in splanchnic organs during administration of volatile anesthetics (3,7), whereas hemorrhage decreases hepatic oxygen consumption in rats (32,33). As data of hepatic venous blood gases are not available in this study, alterations in metabolic demand and oxygen consumption cannot fully be excluded. Reduced splanchnic and hepatic oxygen availability due to a decrease in cardiac output and hemoglobin content, as well as inhomogeneous distribution of capillary perfusion, would contribute most to the significant deterioration of hepatic Pso_2 during hemorrhagic hypotension versus hypotension by volatile anesthetics (20,34–36).

Pancreatic Blood Flow and Oxygenation

In the present study, control pancreatic blood flow was 80 $mL \cdot min^{-1} \cdot 100\ g^{-1}$, representing approximately 1.7% of cardiac output, which accords with results obtained in conscious rats with use of microspheres (16,29,30). We had not expected to find that pancreatic blood flow decreased only slightly (halothane, hemorrhage) or increased beyond control values (enflurane, isoflurane) at a MAP of 50 mm Hg. An earlier study in rats from this laboratory (37) revealed that at graded reductions of MAP by enflurane anesthesia to 50 mm Hg and further to 30 mm Hg, pancreatic blood flow was also maintained, whereas pancreatic vascular resistance progressively decreased. The new inhaled anesthetic sevoflurane preserved pancreatic flow in a similar rat model (14). Choice of animal species and our experimental protocol could have affected the results because others have reported that isoflurane and sevoflurane induced decreased pancreatic perfusion in pigs and dogs from awake controls (3,38).

With regard to our results obtained during administration of volatile anesthetics, we cannot determine whether the observed maintenance of pancreatic blood flow is due to intrinsic pancreatic vascular regulatory phenomena (i.e., autoregulation) or whether it reflects anesthetic-induced vasodilation. Preservation of normal perfusion even during hemorrhagic hypotension strongly suggests a major contribution of intrinsic pancreatic regulation.

Autoregulation of blood flow is defined as the ability of an organ to maintain its blood flow even under changing perfusion pressure. Kvietys et al. (39) characterized the mechanisms involved in the regulation of blood flow and oxygenation of the totally isolated canine pancreas. They concluded that a myogenic component would contribute to pancreatic blood flow regulation because decreased perfusion pressure was associated with a decrease in organ vascular resistance. A metabolic component could not be excluded, because more oxygen was extracted when blood flow was reduced (39). Eliassen et al. (40) demonstrated in rats during papaverine-induced hypotension that pancreatic blood flow increased up to 400% of normotensive values, which indicates considerable capacity for vasodilation. During yohimbine- or propranolol-induced hypotension in rats, increased pancreatic flow was reported (41). According to findings from intravital microscopy (42), the pancreas has a high capillary reserve and vascularity, which could explain the pronounced capacity for pancreatic vascular adaptation (43). During hypotension with sodium nitroprusside at a MAP of 40 mm Hg, pancreatic blood flow increased disproportionally compared with blood flow of other splanchnic organs in dogs (44). The pancreatic vasculature is suggested to be highly reactive to vasodilatory stimuli (43). The mechanism for preservation of pancreatic flow observed in this study remains to be elucidated. Intravital microscopy might be appropriate for studying pancreatic blood flow regulation during hypotensive states.

Despite maintained blood flow, pancreatic Pso_2 was significantly less during hemorrhage compared with volatile anesthetics. Inhomogeneity of perfusion during hypovolemic states has been reported during hypovolemic hypotension. We speculate that such inhomogeneity was responsible for the altered pancreatic tissue Pso_2 also encountered in this study (20,34–36).

Thus, volatile anesthetics at a MAP of 50 mm Hg decreased total hepatic blood flow and tissue oxygen pressures to a similar extent. Isoflurane was associated with the most pronounced pancreatic vessel vasodilation and resulted in pancreatic tissue oxygen pressures higher than normal. The ultimate reason for maintenance of perfusion and oxygenation even at such a low pressure is not clear. Withdrawal of blood to a MAP of 50 mm Hg reduced splanchnic flow, as did the anesthetics. However, hemorrhage was influenced by inhomogeneity of perfusion and deteriorated hepatic and pancreatic tissue oxygen pressures more than by the anesthesia. Therefore the manner in which hypotension is induced also has a profound impact on splanchnic tissue oxygenation.

Propylene glycol (PG) is a widely used vehicle for water-insoluble drugs. Injection of drugs formulated with this solvent often results in pain, thrombosis, or thrombophlebitis that can be reduced by premedication with local anesthetics or opioids. Because osmolality and pH that are unphysiologic may cause these adverse effects, we assessed the contribution of PG to the osmolality of parenteral drug formulations. Osmolality of PG measured in distilled water showed that PG content and osmolality were directly related: 2% wt/vol PG, 264 mOsm/L; 100% PG, 15,200 mOsm/L. The osmolalities of commercially available preparations of drugs dissolved in PG ranged from 365 mOsm/L (2% PG content) to 12,800 mOsm/L (83.46% PG), with most above 1000 mOsm/L. Replacement of PG by a solvent with lower osmolality in Germany has effectively reduced the incidence of side effects for one drug. Until PG can be replaced in drugs, we recommend diluting drugs in a large volume of saline solution; this may help to minimize the undesirable effects of this solvent.

(Anesth Analg 1992;75:431–5)

Pain on injection and thrombosis or thrombophlebitis after intravenous administration of various drugs are frequent, undesired side effects (1–3). Besides causing direct chemotoxic effects, the unphysiologic osmolality and pH of these drugs are mechanisms of inflammation and histologic changes in vessels (4–6) and may cause hemolysis (7). Etomidate, for example, known to be painful on injection and to frequently cause thrombophlebitis (2), has an osmolality of 4965 mOsm/L (8).

Muscle damage and increased creatinine phosphokinase activity in plasma are directly associated with both the volume and the osmolality of substances injected intramuscularly (9). Most of the irritant properties on intramuscular injection of a chlordiazepoxide preparation have been attributed to the osmolality and pH conveyed by propylene glycol (PG), the solvent in which it is prepared and administered (3). Propylene glycol is also the solvent vehicle for many other drugs that anesthesiologists administer, for example, etomidate, nitroglycerin, diazepam, lorazepam, and dexamethasone.

Although the osmolalities of many parenteral drugs often used in anesthesia have been measured, their solvents have not been listed (8). The purpose of this study was to assess the proportion contributed by the solvent PG to the overall osmolality of drug preparations. We measured the osmolality of standard solutions of PG in distilled water and the osmolality and pH of drug formulations containing PG. These values were also determined for two new preparations of etomidate, apparently devoid of venous side effects (2,10), and for propofol, known to be painful on intravenous injection (11).

Methods

Eighteen commercially available drugs for parenteral administration with PG contents ranging from 2% to 83.64% (wt/vol) were investigated. Included were an induction hypnotic, benzodiazepines, corticoids, an antibiotic, five drugs often used by anesthesiologists in emergency or intensive care settings, and diclofenac formulations for intramuscular injection. In addition to PG, 10 of these drugs contained other

solvents or preservatives, such as benzyl alcohol, benzoic acid, ethanol, and sodium disulfite.

Etomidate in lipid emulsion (10% medium-chain triglyceride and 10% soybean emulsion, B. Braun, Melsungen, Germany) and etomidate in hydroxypropyl-β-cyclodextrin (Janssen, Neuss, Germany), two new preparations currently under clinical investigation, were supplied by the manufacturers. Stock solution of PG (Caelo, Hilden, Germany) was used. For dilution we used double-distilled water and commercially available 0.9% saline solution or glucose 5%. Three series of measurements were performed:

1. Osmolality of solutions containing 0%–100% PG dissolved in distilled water.
2. Osmolality and pH of all selected drugs after dilution, as indicated by product information. Etomidate in PG was diluted 1:2 in 0.9% saline solution.
3. Osmolality and pH of seven drugs kept in syringes over a 24-h period. Measurements were performed immediately after drawing the drug into a syringe and after 2, 4, 6, and 24 h. During the first 6 h, syringes were stored at room temperature (23°C) and thereafter in a refrigerator.

Osmolality was measured on an osmometer (Knauer Semi-micro Osmometer, Berlin, Germany) with an analogic, triple-range scale (0–400, 0–800, and 0–1600 mOsm/L). Drugs with osmolality >1600 mOsm/L were diluted 1:10 with double-distilled water using a 1000-μL Eppendorf pipette and a 10 (±0.04)-mL volumetric flask. The result was multiplied by 10. Mean osmolalities were calculated from five different measurements. The coefficient of variation in measurement with this osmometer was ±1%. Values >800 mOsm/L were rounded to the nearest 10. Values of osmolality were also calculated according to the formula of theoretical osmolality:

$$\mathrm{Osm}_{\mathrm{theor}} = \phi n C,$$

where ϕ is the osmotic coefficient ($\phi = 1$); n the number of particles into which each molecule in solution dissociates ($n = 1$); and C the concentration in moles per kilogram (12). The pH value of the drug undiluted in solution was measured using a pH meter and an electrode (WTW pH meter 521 and electrode E50, Weilheim, Germany).

Results

The values of osmolality for standard solutions of PG dissolved in water (Table 1) correspond well with those calculated. Tables 2 and 3 contain osmolality and pH measurements of drugs of interest to anesthesiologists. The graphic presentation of these data show the linear relationship between PG content and the osmolality of the drug preparation (Figure 1).

Table 1. Measured and Theoretical Osmolalities of Standard Solutions of Propylene Glycol Diluted in Distilled Water

Propylene glycol %	Propylene glycol mg/mL	Propylene glycol dissolved in distilled water (mOsm/L)	Calculated theoretical osmolality (mOsm/L)
0	0	0	—
2	20	264	263
10	100	1,440	1,314
20	200	2,570[a]	2,629
40	400	5,350[a]	5,257
60	600	8,300[a]	7,885

Propofol[a]	295	8.2
Propofol (1:4 dilution with glucose 5%)[a]	285	8.1

PG, propylene glycol.
[a]Commercial preparation.

The osmolalities of diclofenac preparations containing at least one additional substance (benzyl alcohol, sodium disulfite, or both, or lidocaine) were between 3150 and 6210 mOsm/L, depending on PG content (194–400 mg/mL). Osmolalities of these preparations were higher than calculated from their PG content. Glucocorticoids for intravenous administration measured were dexamethasone, 2% PG, 365 mOsm/L, and prednisolone, 15% and 20% PG, 1850 and 2970 mOsm/L, respectively.

Osmolality and pH did not change for the following drugs stored in a syringe for 24 h: etomidate, diluted etomidate, etomidate in hydroxypropyl-β-cyclodextrin, etomidate in lipid emulsion, propofol, lormetazepam, diluted lormetazepam, diazepam, and diluted diazepam.

Discussion

Osmolality is a measure of the number of solute particles dissolved in 1 L of solvent. For a given concentration, solutes with a low molecular weight,

such as PG (76.1) or ethanol (46.1), contribute considerably more to the osmolality of a drug formulation than to its weight or volume (13). Figure 1 shows that the drug itself and especially additional solvents and preservatives add to the total osmolality. The measurement of osmolality with the osmometer used had a coefficient of variation of ±1%, a negligible error rate by comparison to that for measurement after dilution and supercooling.

Propylene glycol (1,2-propanediol), a polyhydric alcohol, is a viscous, colorless liquid widely used as a solvent for water-insoluble drugs and as a preservative in parenteral, oral, and topical formulations. It is regarded as less toxic than other glycols and is harmless when taken orally, with acceptable daily oral intake estimated at 25 mg/kg (13). Propylene glycol is metabolized by hepatic alcohol and aldehyde dehydrogenases to pyruvate and lactate, which can enter gluconeogenic pathways. It does not accumulate in organ tissues, but plasma levels of PG may increase rapidly with impaired renal function (14,15).

In recent years there have been many reports about side effects with PG. Hyperosmolality, increased osmolal gap, and lactic acidosis are considered responsible for neurologic symptoms, including stupor, coma, and seizures (14–16). Cardiovascular disturbances including sinus arrhythmia (17), cardiorespiratory arrest (18), myocardial infarction, and asystole (19) have been associated with drugs containing PG. Pentobarbital anesthesia in sheep resulted in pulmonary hypertension attributed to PG (20). In rats, both PG and etomidate diluted with PG inhibited the hepatic metabolism of enflurane (21).

The most frequent adverse effects are pain on intravenous injection and thrombophlebitis (1,2). Histology after injection of a diazepam formulation containing PG and of PG alone revealed vessel dilation, interstitial edema, and polymorphonuclear leukocyte infiltration with subsequent thrombotic organization. Addition of lidocaine did not alter the inflammatory reaction (4).

In vitro studies reported hemolysis when PG had been added in various concentrations to blood samples (22); however, hemolysis has also been observed in animals (7,23) and in humans (16). Radiologists have long been aware of the detrimental effects of high osmolality contrast media on cells. Erythrocyte damage is caused by loss of intracellular fluid, leading to formation of desiccocytes, which, because of rigidity, can decrease capillary blood flow and increase pulmonary arterial pressure (23). Endothelial damage led to increased permeability in rat aortic endothelium at threshold levels of approximately 1400–1600 mOsm/L (5). Hyperosmotic solutions have triggered histamine release from human basophils in vitro (24). Finally, heparin resistance has been attributed to a protaminelike effect of PG (25).

To reduce the uncomfortable sensations for patients receiving etomidate, premedication with local anesthetics or opioids is common. Premedication,

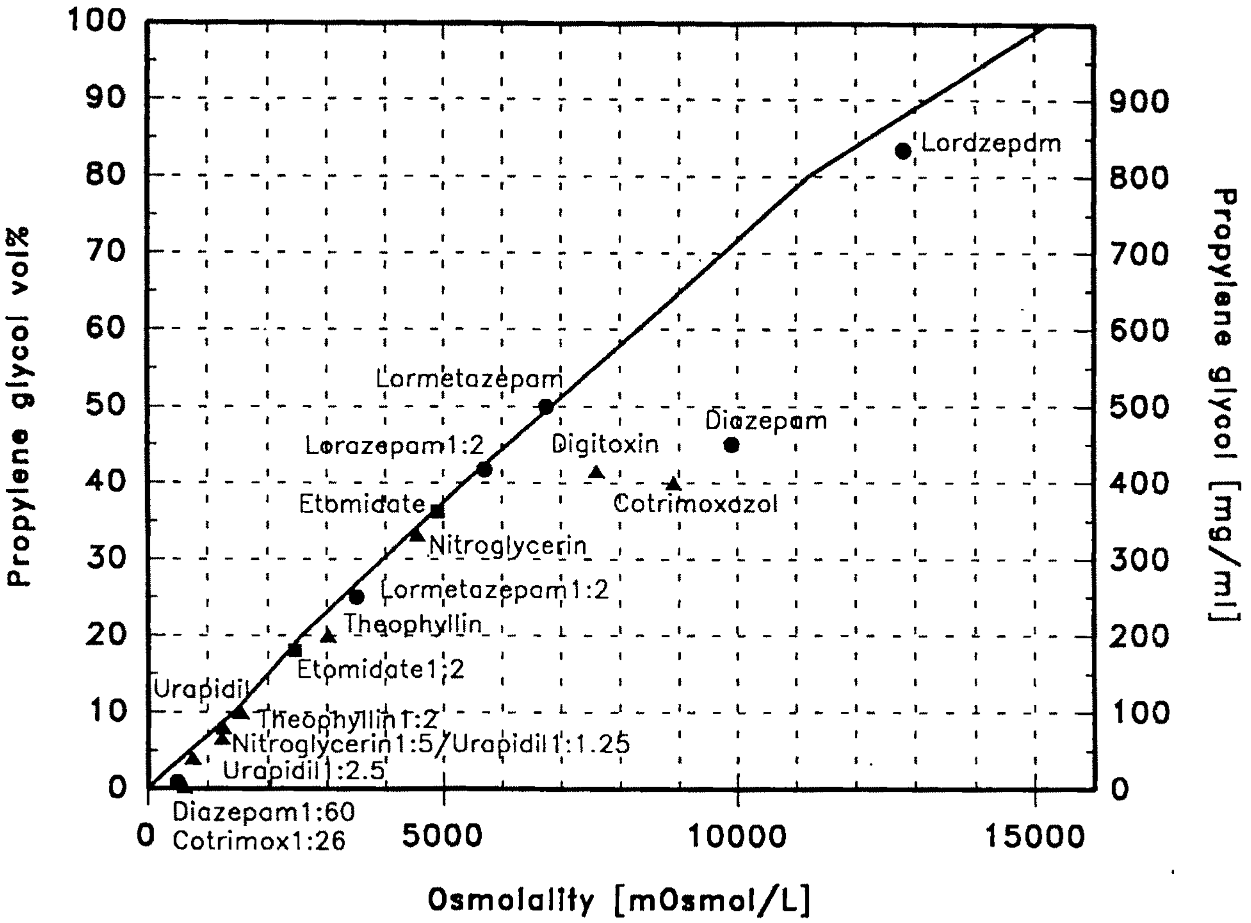

Figure 1. Propylene glycol content and osmolality of various drugs administered parenterally. *Solid line*, standard solutions of PG in distilled water; *squares*, formulations of etomidate; *circles*, the benzodiazepines; *triangles*, various drugs used in anesthesia (see Table 3).

however, does not abolish the underlying mechanism of tissue damage. Limited hemolysis and the release of mediators such as histamine are difficult to detect, and the venous sequelae that may arise during the first or second week after an operation are not always seen by an anesthesiologist.

Osmolalities of diclofenac preparations of >3000 mOsm/L cause pain on intramuscular injection and an increase in mean creatinine phosphokinase plasma activity by 120 mU/mL (3,9). Drug preparations tested that use PG as a solvent vehicle have osmolalities >1000 mOsm/L, with most >3000 mOsm/L. These values exceed those of hyperosmolar solutions that produced pain sensation in veins on the back of the hand after infusion (1.5 mL/min) or injection (1 mL/s) (6).

Diluting a drug reduces its osmolality. Osmolality is reduced by half, for example, in dilution of a drug with an equal volume of distilled water (designated 1:2); however, large volumes would have to be infused to reduce osmolality of some drugs to near plasma osmolality, 285–295 mOsm/L. Thus, necessary dilution is seldom practicable for intramuscular administration when large volumes are unacceptable. All drugs except nitroglycerin (3.7) have pH values between 4 and 11, below and above which levels pain is evoked (6).

Pharmaceutical manufacturers in the United States are not required to report the osmolalities of their drug preparations. Most package inserts of the drugs we tested listed pain and venous sequelae as possible adverse effects without giving their cause. Package inserts warned against intraarterial injection of etomidate (35% PG), lormetazepam (50% PG), and lorazepam (84% PG) because of subsequent necrosis, and mandated dilution for lorazepam and cotrimoxazol (41.4% PG).

We believe that it might be beneficial to reduce the osmolality of drug formulations to more physiologic levels and to reevaluate the use of PG in parenteral drug formulations such as nitroglycerin solutions (16). Replacement of PG in formulations of diazepam (1) and of etomidate (2,10) has successfully reduced adverse effects. Possibly, new solvents such as 2-

hydroxypropyl-β-cyclodextrin or a lipid emulsion may prove to be better alternatives.

We thank Dr. Viktoria Mönch and Dr. Wolfgang Breugst of the University Pharmacy, Munich, for their assistance in performing the measurements and providing the drugs.

Sevoflurane Is Biotransformed by Guinea Pig Liver Slices but Causes Minimal Cytotoxicity

Hanan N. Ghantous, PhD, Jeanne Fernando, BS, A. Jay Gandolfi, PhD,
and Klaus Brendel, PhD

Departments of Anesthesiology and Pharmacology, College of Medicine, University of Arizona, Tucson, Arizona

Guinea pig liver slices were used to evaluate the biotransformation and hepatotoxic potential of sevoflurane. Precision-cut liver slices (250–300 μm thick) were incubated in sealed roller vials in buffer at 37°C under 95% O_2. Sevoflurane was added to produce 0.9 or 2.1 mM medium concentrations. After incubation (6–24 h), the intracellular K^+ content and protein synthesis were determined, along with the defluorination of sevoflurane. Isoflurane was included for comparative purposes. Sevoflurane (2.1 mM) and isoflurane (2.3 mM) had no effect on slice K^+ content, but both anesthetics depressed protein synthesis. The biotransformation of sevoflurane was maximal at 95% O_2, with threefold more F^- produced from sevoflurane than isoflurane. Sevoflurane appears to have a minimal effect on the guinea pig liver slices, which is consistent with in vivo studies in which minimal or no hepatotoxicity has been observed.

(Anesth Analg 1992;75:436–40)

Sevoflurane is a fluorinated inhaled anesthetic currently undergoing clinical trials. It provides rapid induction to and awakening from anesthesia owing to its low blood-gas partition coefficient (1). When sevoflurane was examined in rats and dogs, no toxicologic changes were seen even after frequent exposure over 2 wk; however, other preliminary studies in guinea pigs showed biochemical and histologic evidence of sevoflurane-induced hepatotoxicity (2). Additionally, when Franks et al. (3) studied the effect of volatile anesthetics on the synthesis of proteins in perfused rat livers, sevoflurane depressed the synthesis of albumin, fibrinogen, and transferrin at clinically relevant concentrations. Further studies are needed to completely understand the hepatotoxic potential of sevoflurane.

In the rat, dog, and humans, sevoflurane is biotransformed to inorganic F^- and hexafluoroisopropanol. Hexafluoroisopropanol is excreted in the urine as a glucuronide conjugate in the rat (4) and in humans (5). The glucuronide conjugate of hexafluoroisopropanol has also been detected in the bile of rats exposed to sevoflurane (6). Hexafluoroisopropanol is toxic to mice with a median lethal dose of 300–600 mg/kg (7). These investigators observed hexafluoroisopropanol to have central nervous system-depressant properties. In humans, sevoflurane appears to undergo limited biotransformation (1%–4% of the absorbed dose) and to have little or no systemic toxicity (8). No abnormalities in liver function were reported when volunteer trials were performed with sevoflurane (5,8).

The dynamic organ culture of precision-cut guinea pig liver slices is a suitable in vitro method to study the biotransformation and hepatotoxic potential of volatile anesthetics (9,10). Guinea pig liver slices can biotransform volatile anesthetics at rates comparable to those observed in vivo. Cytotoxicity of the volatile anesthetics in these liver slices can be monitored by measuring the leakage of intracellular K^+ ion from the slices and their effect on protein synthesis and secretion (10,11).

The object of this study was to determine the biotransformation and hepatotoxic potential of sevoflurane by using a sensitive in vitro system in a responding species.

Methods

The protocol for the animal studies was approved by the Animal Care and Use Committee of the University of Arizona. Adult male Hartley guinea pigs (600–650 g) are a good species and strain for studying volatile anesthetic-associated hepatic injury (12). The

animals were obtained from Sasco, Inc. (Omaha, Neb.) and housed five animals per hanging cage on a 12-h light/dark cycle for a few days before the experiments. The guinea pigs were fed Wayne Lab Chow, cabbage, and water ad libitum.

After cervical dislocation of the animals, the liver was excised and immediately placed in cold Krebs-Henseleit buffer (4°C, pH 7.4) that contained (in grams/liter) NaCl 6.9, KCl 0.36, KH_2PO_4 0.13, $NaHCO_3$ 2.11, $MgSO_4 \cdot 7\ H_2O$ 0.29, $CaCl_2 \cdot H_2O$ 0.43, and glucose 4.5 (9,10). Cores (1 cm in diameter) were taken from different areas of the liver. Cores were sliced (25-30 mg wet wt, 250-300 μm thick) with a Krumdieck tissue slicer (13). Slices were maintained on ice in oxygenated (95%:5%, O_2/CO_2) Krebs-Henseleit buffer pH 7.4 until incubated.

Glass scintillation vials containing 1.6 mL of Krebs-Henseleit buffer (supplemented with 1.7 g/L of $NaHCO_3$, to obtain pH 7.4 at 37°C, and 1 mM each of basal medium Eagle [BME]-vitamins, BME-amino acids, *l*-glutamine, and 50 μg/mL gentamycin) were used for incubation. Three slices were incubated together on stainless steel mesh cylinders circumscribed with two wheels. Vials were usually gassed with 95% O_2/5% CO_2 except in the biotransformation studies, where the O_2 was varied between 2.5% and 95%. After 1-h preincubation, the volatile anesthetics were administered by injection through a Teflon septa cap onto a circular filter paper wick (diameter 2.2 cm). Hexafluoroisopropanol was delivered directly to the incubation medium. Vials were placed on a heated (37°C) vial rotator, housed in an acrylic plastic box, and rotated at 3.5 rpm for up to 24 h. Slices were removed after 6, 12, and 24 h and used for measuring K^+ levels, DNA content, and protein synthesis. In separate exposures, the slices and medium were collected together and used for measuring metabolites.

Aliquots of the incubating medium were extracted with *n*-heptane and the extract assayed for sevoflurane and isoflurane by gas chromatography (14). Sevoflurane or isoflurane (0.5-4 mM) in *n*-heptane was used for preparing a standard curve.

The F^- concentrations were measured with an ion-selective electrode (Onion Research, Cambridge, Mass.). Standard F^- solutions with sodium fluoride (1-2 mM) were prepared and carried through the same procedure as the sample (9); F^- production is expressed as picomoles F^- per milligram slice weight.

Slices for K^+ and DNA analysis were blotted and placed in 1 mL of deionized water and homogenized. The K^+ content was measured by flame photometry, and the DNA content of the slice was measured by a fluorometer assay and used to normalize K^+ values (10). For the analysis of protein synthesis, slices were incubated in the presence of 0.3 μCi [^{3}H]leucine per milliliter medium, blotted, homogenized in 1 mL ice-cold 1 N KOH, and assayed for protein synthesis (11). Results were expressed as disintegrations per minute (dpm) ^{3}H incorporated per milligram protein.

Chemicals

Sevoflurane was obtained from Maruishi Pharmaceutical Co. (Osaka, Japan). Isoflurane was obtained from Anaquest (Murray Hill, N.J.). *l*-Leucine-(4,5-^{3}H) (53 μCi/mmol) was obtained from ICN Biomedicals, Inc. (Irvine, Calif.). Hexafluoroisopropanol was obtained from Sigma Chemical Company (St. Louis, Mo.). *l*-Glutamine, BME-amino acids, BME-vitamins, and gentamycin were purchased from Gibco Laboratories (Grand Island, N.Y.). All other chemicals were of analytical grade and obtained from regular commercial sources.

Experiments were repeated four to five times with slices from different animals. For each experimental condition, six slices were used. Thus, 24-30 slices were assayed for each experimental point. Values were given as mean ± SEM. Comparison of values was made with a one-tailed Student's *t*-test.

Results

As with previous anesthetic studies (9-11), liquid sevoflurane (10 and 30 μL) was injected on the filter paper wick and allowed to vaporize to produce media concentrations of 0.9 and 2.1 mM. A smaller volume of isoflurane (20 μL) produced a concentration of 2.3 mM in the medium. The difference in the concentrations of the different anesthetics is due to differences in partition coefficients. The concentration of the anesthetic was maintained throughout the incubation period. This was found to be an easy and reproducible method for delivering a constant concentration of sevoflurane in the incubation medium. It should be noted that these media concentrations exceed the concentration (0.7 mM) observed in blood during sevoflurane anesthesia (15). It is at these concentrations, however, that the following effects were seen.

Sevoflurane defluorination was dependent on the O_2 tension (Figure 1). Optimal defluorination occurred in a 95% O_2 atmosphere (720 ± 115 pmol·mg slice $wt^{-1} \cdot 6\ h^{-1}$). A 2.5% O_2 atmosphere decreased the defluorination rate to 124 ± 22 pmol·mg slice $wt^{-1} \cdot 6\ h^{-1}$. Microwave-killed slices (60 s) defluorinated sevoflurane at only 39 pmol·mg slice $wt^{-1} \cdot 6\ h^{-1}$ under 95% O_2, indicating the minimal nonenzymatic degradation of sevoflurane. After exposing the slices to 2.3 mM isoflurane, F^- production was 190 ± 15 pmol $F^- \cdot$mg slice $wt^{-1} \cdot 6\ h^{-1}$ under 95% O_2 atmosphere.

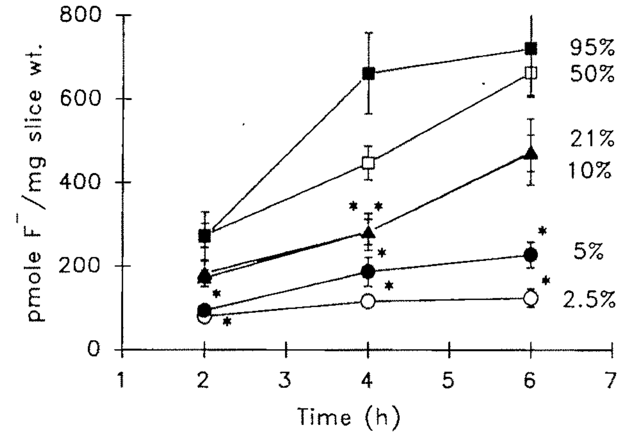

Figure 1. Defluorination of sevoflurane by guinea pig liver slices under different O_2 atmospheres. Each point represents the mean ± SEM; n = 24–30 liver slices from four to five separate animals. Sevoflurane concentration in the media was 0.9 mM. *Significant difference from value measured under 95% O_2 atmosphere ($P <$ 0.05).

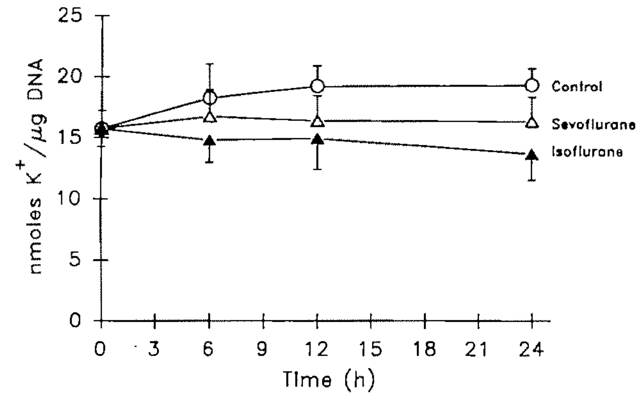

Figure 2. Effect of sevoflurane and isoflurane on guinea pig liver slice K^+ content. Liver slices were incubated with 2.1 mM sevoflurane or 2.3 mM isoflurane for 24 h in 95% O_2. Values are means of nmol $K^+/\mu g$ DNA ± SEM; n = 24–30 liver slices from four to five animals.

Guinea pig liver slices were exposed to either 2.1 mM sevoflurane or 2.3 mM isoflurane for 24 h under 95% O_2 atmosphere (Figure 2). Both sevoflurane and isoflurane had no statistical effect on the intracellular K^+ content of the liver slice, which has proved to be a reliable, early indicator of cytotoxicity (10). Both sevoflurane (2.1 mM) and isoflurane (2.3 mM) caused a significant depression (40%–50% of control) in protein synthesis in the liver slice (Figure 3) after exposure for 24 h under 95% O_2 atmosphere.

Hexafluoroisopropanol produced a time- and concentration-dependent decrease in liver slice K^+ content (Figure 4). Although 0.1 mM hexafluoroisopropanol did not alter slice K^+ content, 0.3 mM produced a linear decrease from 0 to 24 h. At a higher concentration (0.6 mM), a substantial decrease in slice K^+ content was evident by 6 h.

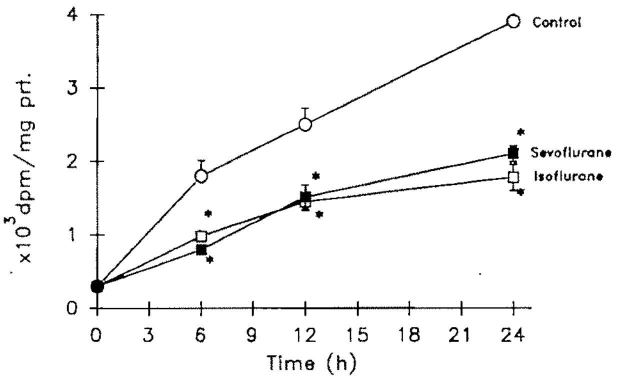

Figure 3. Effect of sevoflurane and isoflurane on protein synthesis in the guinea pig liver slices. Liver slices were exposed to 2.1 mM sevoflurane or 2.3 mM isoflurane for 24 h in 95% O_2. Values are means of disintegrations per minute (dpm) ^3H incorporated/mg protein (prt.) ± SEM; n = 24–30 liver slices from four to five animals. *Significantly different from control ($P <$ 0.05).

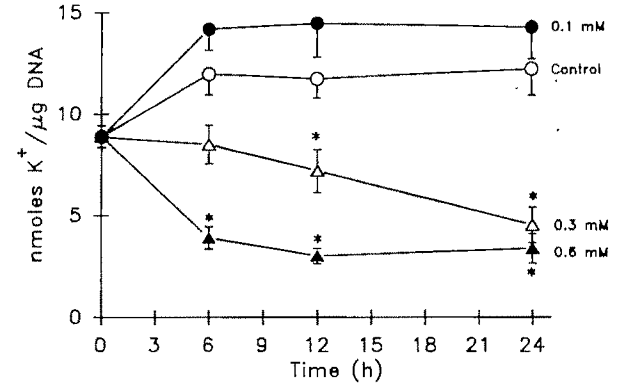

Figure 4. Effect of hexafluoroisopropanol on guinea pig liver slice K^+ content. Liver slices were exposed to three different doses of hexafluoroisopropanol under 95% O_2. Values are means ± SEM; n = 24–30 liver slices from four to five animals. *Significant differences ($P <$ 0.05) from the control value.

Discussion

The use of cultured guinea pig liver slices offers an approach that is suitable to study the biotransformation and hepatotoxic potential of volatile anesthetics (9–11,16). Although sevoflurane was readily biotransformed by the guinea pig liver slices, neither it nor the products of the biotransformation were cytotoxic to the liver slices. In addition, the primary organic metabolite, hexafluoroisopropanol, was not found to be toxic at concentrations produced by biotransformation of sevoflurane.

The rate of sevoflurane defluorination was dependent on the O_2 tension of the incubation; however, a decrease from normoxic tension (21% O_2) to hypoxic

(10% O_2) had no effect on the rate of defluorination. It is only as the O_2 tension decreased to 5% and 2.5% that the rate of defluorination was substantially decreased. Conversely, a doubling of the O_2 tension (21%–50% O_2) almost doubled the rate of defluorination. A 95% O_2 atmosphere further enhanced the rate of defluorination, but by 6 h there was no difference in the quantity of fluoride produced from slices under 95% O_2 versus 50% O_2. It should be pointed out that the O_2 tension does not absolutely reflect the dissolved O_2 in the medium nor the O_2 level throughout the slice (10). This would explain the lack of linearity at all O_2 tensions relative to sevoflurane defluorination. Overall, however, it is very evident that sevoflurane defluorination is O_2 dependent, as would be expected when one examines the products of past biotransformation studies (4–6).

Biotransformation appears to be important in producing hepatotoxicity by volatile anesthetics (12). Sevoflurane is known to be biotransformed to inorganic fluoride and to hexafluoroisopropanol (4,5). Fluoride production from sevoflurane in the guinea pig liver slices was much larger than that in the presence of isoflurane. Although sevoflurane undergoes considerable metabolism (17,18), and peak fluoride concentrations of fluoride ion approach nephrotoxic values, there has been no evidence of gross changes in renal function in either animals or humans (8,17,18).

Liver slices were used from guinea pigs because this species better resembles humans with regard to acute and mild cases of hepatic dysfunction associated with clinical halothane anesthesia (19,20). Although preliminary studies reported that sevoflurane produced a liver lesion in the guinea pig (2), the lesion was of the type produced by ischemia or hypoxia. A number of laboratories are currently examining the effect of sevoflurane on hepatic performance (21). Our liver slice system can examine the direct chemotoxic potential of sevoflurane but would not be the appropriate system to discern the effect of sevoflurane-induced hepatic ischemia or hypoxia.

Although sevoflurane and isoflurane had no effect on the intracellular K^+ content of the liver slice, both anesthetics depressed the rate of protein synthesis. Previous studies have shown that protein synthesis can be a more sensitive indicator of the early cellular alterations produced by mild toxicants such as volatile anesthetics than changes in the intracellular K^+ content of the slice (11). The depression of protein synthesis by sevoflurane in these studies confirms the work of Franks et al. (3), in which sevoflurane depressed synthesis of albumin, fibrinogen, and transferrin in the isolated perfused rat liver; however, the decrease in protein synthesis caused by sevoflurane was much less than that produced by halothane, which almost completely inhibits the process in liver slices (11).

Hexafluoroisopropanol has been reported to have central nervous system-depressant properties in mice with a median lethal dose of 300–600 mg/kg (7). The studies presented here demonstrate that hexafluoroisopropanol is cytotoxic to liver slices at concentrations of 0.3 mM and above. As there is a stoichiometric production of fluoride ion and hexafluoroisopropanol during the biotransformation of sevoflurane, blood fluoride ion levels after sevoflurane anesthesia are an indicator of the hexafluoroisopropanol produced (4,8). Blood fluoride levels are usually <30 μM; thus, an equivalent amount of hexafluoroisopropanol would be produced. Therefore it is unlikely that toxic concentrations of hexafluoroisopropanol will be produced from sevoflurane. Furthermore, hexafluoroisopropanol appears to undergo glucuronide conjugation readily, further minimizing a buildup of its concentration in either the liver or blood (6).

Overall, sevoflurane has the same effects on the guinea pig liver slices as isoflurane, which is considered the least hepatotoxic of the currently used volatile anesthetics. Although the metabolites of sevoflurane (fluoride ion and hexafluoroisopropanol) have toxic potential, they are formed in low enough quantities to not present any problems (18).

We thank Patricia Kime and Sallie Cochren for their assistance in preparing and typing this manuscript. We also acknowledge Willis Perley for his technical assistance.

A Cysteine-for-Arginine Substitution (R614C) in the Human Skeletal Muscle Calcium Release Channel Cosegregates With Malignant Hyperthermia

Kirk Hogan, MD, Fergus Couch, BSc, Pat A. Powers, PhD, and Ron G. Gregg, PhD

Departments of Anesthesiology and Pediatrics, and The Waisman Center on Mental Retardation and Human Development, University of Wisconsin, Madison, Wisconsin

A point mutation in the human gene for the skeletal muscle calcium release channel (ryanodine receptor [RYR1]) correlates with inheritance of malignant hyperthermia in a family of Northern European descent. The substitution of thymine for cytosine at position 1840 of the RYR1 transcript results in a cysteine-for-arginine substitution at position 614 (R614C) of the amino acid sequence. The mutation was absent in 59 normal individuals from the general population, in 61 additional unrelated malignant hyperthermia-susceptible patients, and in 18 patients with malignant hyperthermia associated with other inherited or congenital diseases. Together with reports of an equivalent mutation in six susceptible pig strains and an identical mutation in one other human pedigree, these findings suggest that the cysteine-for-arginine mutation represents a shared calcium release channel pathogenesis between porcine malignant hyperthermia and a subset of mutations responsible for the human malignant hyperthermia syndrome.

(Anesth Analg 1992;75:441–8)

Malignant hyperthermia (MH) is a pharmacogenetic myopathy elicited by widely used volatile anesthetic agents and depolarizing muscle relaxants (1). The syndrome consists of skeletal muscle rigidity, rhabdomyolysis and myoglobinuria, elevated creatine phosphokinase, hypercapnia, hyperkalemia, metabolic and respiratory acidosis, cardiac arrhythmia, and heat production. Prophylaxis and treatment with dantrolene is usually effective, although coagulopathy, renal failure, cerebral edema, coma, and death may still occur despite early detection and therapy. An estimate of the patient's perioperative risk is therefore imperative before administration of drugs capable of initiating MH.

Laboratory diagnosis of MH rests on the measurement of contracture tension generated in electrically stimulated muscle strips in the presence of halothane and caffeine. The contracture test is invasive, expensive, and time-consuming. Owing to fears of permanent disfigurement, the test is contraindicated in children weighing <20 kg, a population at substantial risk for MH. Because MH predisposition is inherited in many if not all cases, an improved method of risk assessment has been sought directly in the genetic constitution of susceptible patients. Linkage between polymorphic markers and porcine MH (2,3) facilitated assignment of the locus for halothane sensitivity to chromosome 6 of the pig (4) in a region conserved as a syntenic cluster on the proximal long arm of human chromosome 19. By virtue of its mapping to an identical position within the syntenic regions of both species (5,6), the gene encoding the skeletal muscle calcium release channel, also termed the ryanodine receptor (RYR1), became a candidate gene for the MH mutation. Altered structural and functional properties of the calcium release channel (7–9) are thought to underlie the pronounced defect in regulation of myoplasmic calcium that characterizes MH (10–12). RYR1 gates the release of calcium from the sarcoplasmic reticulum in response to the spread of depolarization from the neuromuscular junction throughout the T-tubule system. Convergent genetic and biochemical data pointing to a disorder of this protein led to the sequencing of the normal and MH pig RYR1 alleles in their entirety (13). A substitution of a thymine for a cytosine at nucleo-

Figure 1. A region of RYR1 DNA amplified by PCR indicating the relative positions of oligonucleotide primers 1, 2, and 3. *Numbers* refer to the nucleotide sequence of the RYR1 cDNA. *The sequence beneath primer 2* is complementary to that of the oligonucleotide used for PCR (see text). Primers 1 and 2 amplify a 74-base pair (bp) band in both genomic and cDNA. Primers 2 and 3 amplify a 2-kilobase (kb) band in genomic DNA. *Dots* interrupting the numbered cDNA sequence from 1641 to 1807 represent a region of genomic DNA containing at least two introns. Underlying the middle base of each codon is the corresponding amino acid designated by its one-letter code. The C → T nucleotide substitution and the arginine-to-cysteine amino acid substitution are highlighted.

tide 1843 was found to produce a cysteine-for-arginine substitution at position 615 in the porcine RYR1 amino acid sequence (13). The association of the RYR1 C1843 → T mutation with porcine MH has subsequently been reported in more than 450 pigs representing all six breeding strains investigated (14).

Human chromosome 19q markers within and adjacent to the RYR1 locus are tightly linked to the MH phenotype in 17 Canadian (15) and 3 Irish families (16,17). Gillard et al. (18) recently documented inheritance of a mutation equivalent to the pig substitution in 1 of 35 human MH pedigrees studied. In that family, a thymine-for-cytosine mutation at position 1840 causes a cysteine-for-arginine substitution at position 614 of the amino acid sequence (R614C). The human RYR1 C1840 → T substitution eliminates a *Rsa*I restriction endonuclease site that may be used to survey a population and to follow the mutation in a pedigree. We report a second human pedigree with cosegregation of the R614C mutation and MH, identified by screening 62 unrelated MH-susceptible subjects, 18 patients with MH associated with other inherited or congenital disorders, and 59 normal subjects.

Methods

Patients

The protocol for this study was approved by the University of Wisconsin Human Subjects Committee, and all participants gave informed consent. Patients were recruited in response to letters in scholarly journals, through meetings and newsletters of the Malignant Hyperthermia Association of the United States (MHAUS), and by referral from halothane-caffeine contracture test laboratories.

Subjects from 62 families with clinical and contracture test evidence for MH were studied: 55 families were from North America; 5 were from New Zealand, and 2 were from Iceland. When available, probands with fulminant MH events were selected for DNA analysis. Families in which the proband died during the clinical event or was otherwise not available were represented by a relative of the proband with a positive contracture test. Patients surviving events resembling MH in association with the following inherited or congenital disorders were also investigated for the concomitant presence of the R614C substitution: four with King-Denborough syndrome; two with central core disease; and one each with Duchenne's muscular dystrophy, Becker's muscular dystrophy, neurofibromatosis, tuberous sclerosis, osteogenesis imperfecta, hemorrhagic shock encephalopathy, multiple exostosis, Treacher-Collins syndrome, Turner's syndrome, Smith-Lemli-Opitz syndrome, Osler-Weber-Rendu syndrome, and Pearlman's syndrome. Fifty-nine unrelated persons from the general population with no history of neuromuscular disease were also examined. Cases from related families were excluded.

Genomic DNA Isolation

Blood samples were collected in ACD Solution A preservative (Becton Dickinson Vacutainer Systems) and shipped by overnight mail at ambient temperature. Genomic DNA was prepared from either peripheral blood lymphocytes or lymphoblastoid cell lines by nuclear isolation and lysis, protease digestion, and ethanol precipitation (19).

Polymerase Chain Reaction

Amino acid 614 in RYR1 is encoded by residues 1840–1842 in the nucleotide sequence of the mRNA. Primers were designed that closely flank nucleotide 1840 and amplify a 74-base pair (bp) fragment between nucleotides 1808 and 1881 in the mRNA of the RYR1 gene by polymerase chain reaction (PCR) (20) (Figure 1). Primer 1,5′-GCTCCCTGTGTGTGTG TAATGGTG-3′ from nucleotides 1808–1831 and primer 2,5′-GCCAGGCAGCAAGTTCTCAG-3′ complementary to nucleotides 1881–1862 of the RYR1 mRNA were synthesized by the University of Wisconsin-Madison Biotechnology Center. The PCR con-

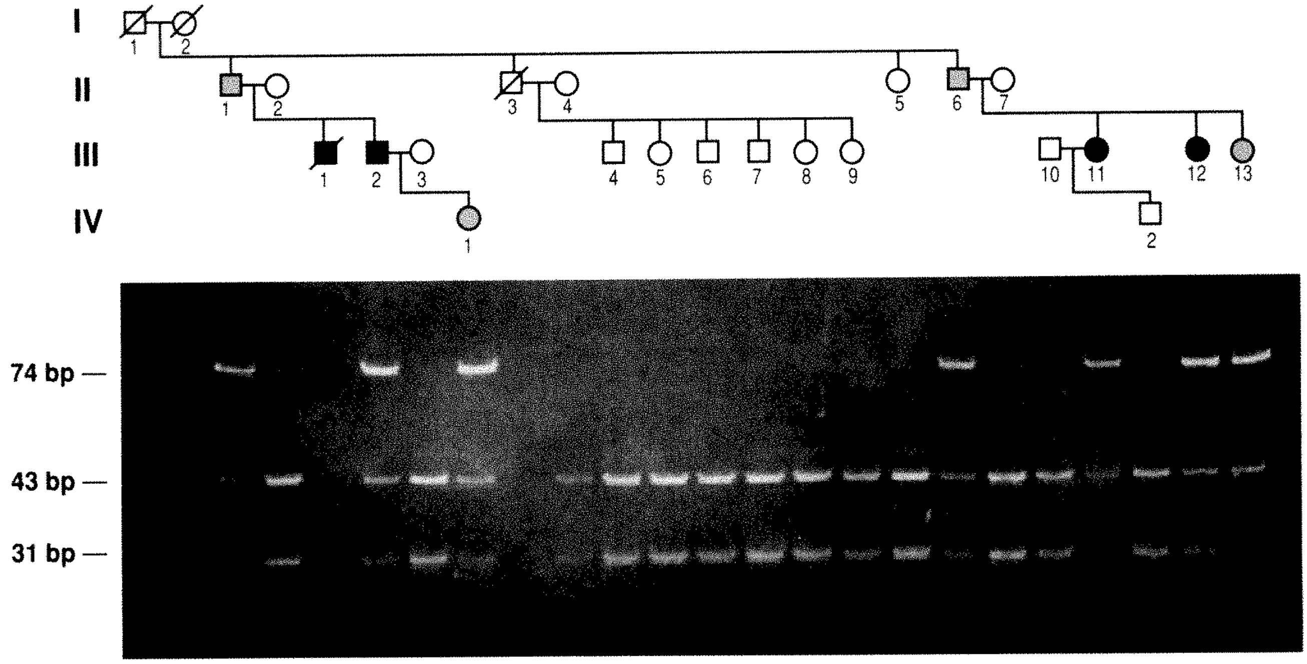

Figure 2. (**Top**) A four-generation pedigree that includes 25 persons. The proband is III-1. *Solid pedigree symbols*, MH-affected persons diagnosed by clinical event or contracture test; *shaded symbols*, persons heterozygous for the R614C mutation. (**Bottom**) Photograph of DNA fragments produced by PCR with oligonucleotide primers 1 and 2 (shown in Figure 1), followed by digestion with *Rsa*I and separation on a 20% acrylamide gel. The normal gene is identified by the presence of a cleavage site creating 43- and 31-base pair (bp) fragments. The 74-bp fragment is from the mutant allele. Thus, normal homozygotes have the site on each chromosome, with each producing two bands. The MH-affected heterozygote is distinguished by the presence of three bands; the normal chromosome produces the 43- and 31-bp bands, and the mutant chromosome produces the larger 74-bp band. *Empty lanes* are aligned beneath deceased individuals.

ditions were as follows: denaturation at 93°C for 3 min, followed by 32 cycles of denaturation at 93°C for 1 min, annealing at 54°C for 45 s, and extension at 72°C for 30 s, with a final extension step of 7 min at 72°C using a programmable thermal controller (MJ Research). The PCRs contained 500 ng of genomic DNA, 200 μM of each deoxynucleotide, 20 pmol of each primer, 50 mM KCl, 1.5 mM $MgCl_2$, 10 mM Tris-HCl pH 8.3, 0.001% gelatin, and 1.25 U of Taq DNA polymerase (Perkin-Elmer Cetus) in a total volume of 50 μL.

Primer 3,5′-CACAAACTTGGACTGGCTGGT-3′ from position 1620 to 1640 of the RYR1 mRNA was used to amplify a 2-kilobase (kb) fragment of genomic DNA when used with primer 2 (Figure 1). The PCR conditions were as follows: denaturation at 94°C for 3 min, followed by 35 cycles of denaturation at 94°C for 1 min, annealing at 64°C for 1 min, extension at 72°C for 3 min, and a final extension step of 10 min at 72°C. Other PCR conditions were as described earlier.

Detection of the RsaI *Site*

The mutation thought to be responsible for porcine MH would result in the destruction of an *Rsa*I site in the human RYR1 gene. Therefore, DNA from each subject to be tested was amplified with primers 1 and 2 (Figure 1), and half of the product was digested with 2 U of *Rsa*I (Promega) in a total volume of 40 μL for 4 h. Digested DNA was analyzed on a 20% acrylamide gel, run overnight at 8 V/cm in 45 mM Tris-Borate pH 8.3, 1 mM EDTA. Gels were stained with ethidium bromide and photographed under ultraviolet light. In samples heterozygous for the *Rsa*I site, internal controls were added to ensure that the results were not due to partial restriction digests.

Malignant Hyperthermia Diagnosis and Pedigree

Loss of the *Rsa*I recognition site was found in the brother (III-2) of the deceased proband (III-1) of the MH pedigree depicted in Figure 2. The proband's past medical history was significant only for an uncomplicated tonsillectomy with halothane, nitrous oxide, and succinylcholine anesthesia at age 5 yr. On admission, the patient was afebrile, with a normal physical examination and laboratory evaluation. He was premedicated first with prochlorperazine (10 mg IM) and pentazocine (30 mg IM), then with meperidine (75 mg IM), secobarbital (50 mg IM), and atropine (0.5 mg IM) immediately before surgery. Induction of anesthesia with sodium thiopental (300 mg IV) and succinylcholine (100 mg IV) was accompanied with "violent spastic movements" and a tight jaw, although endotracheal intubation was performed on the first attempt. Anesthetic maintenance consisted of 20% cyclopropane in 80% oxygen. Tachypnea was seen after additional succinylcholine during opening and closing of the peritoneum, and the skin was observed to be dusky and warm. At wound closure, hypotension and tachycardia preceded ventricular fibrillation, which was successfully treated with open cardiac massage, epinephrine, and sodium bicarbonate. The patient failed to regain consciousness. In retrospect it was noted that the fresh carbon dioxide absorbent was exhausted after only 40 min rather than the usual 2 h. The ensuing 24 h were characterized by hyperthermia (39.9°C), persistent myoglobinuria, arrhythmia, edematous extremities requiring fasciotomy, hyperkalemia (6.6 mEq/L), elevated creatinine phosphokinase (value not available), and metabolic acidosis. The patient died of cardiac arrest on the second postoperative day after 1.5 h of resuscitation. The autopsy showed swollen skeletal muscle fibers with obliteration of cross-striations, acute renal tubular necrosis, pulmonary congestion, and cerebral edema with signs of hypoxic injury.

The proband's family is of Northern European descent currently residing in the United States. His father (II-1) reported persistent muscle aches after anesthesia for dental extraction that included an unspecified muscle relaxant and sodium thiopental. The proband's brother (III-2) had a muscle biopsy and halothane-caffeine contracture test at age 34 yr (Hahnemann University, 1984). His history was significant for frequent muscle cramps and an episode of myoglobinuria during vigorous exercise. Muscle histology showed mild, nonspecific changes. Two muscle strips developed 2.5-g and 1.3-g contractures to 3% halothane (normal <0.7 g). The responses to caffeine were normal (0.2 g at 2 mM caffeine). Two female first cousins (III-11, III-12) also had contracture tests. They and their parents reported uncomplicated anesthetics in the past. One cousin (III-11) complained of occasional muscle cramps. Histologic investigation of her muscle showed type II muscle atrophy, with increased lipid droplets and aggregates of mitochondria on ultrastructural examination. A strip of her muscle developed 1.3-g contracture to 1% halothane (normal <0.5 g), and a normal response to caffeine (Hahnemann University, 1982). The proband's other female cousin (III-12) denied muscle cramping or other neuromuscular complaints. Two biopsy specimens from her deltoid muscle (Loyola University, 1987) generated 1.2 g and 1.4 g of tension in 3% halothane (normal <0.7 g) and 0.7 g and 0.6 g tension in 2 mM caffeine (normal <0.3 g). Muscle histology was not reported. The remainder of the family denied neuromuscular complaints, anesthetic complications, or other inherited diseases.

Digestion and Cloning

The restriction enzyme *RsaI* has a four-base recognition sequence (GTAC), and alteration of any one of these nucleotides would destroy the cleavage site. To determine whether the nucleotide substitution causing loss of the endonuclease recognition site also encodes an amino acid substitution, the region surrounding the mutation was sequenced. A 2-kb genomic DNA fragment amplified from patient III-2 with primers 2 and 3 was purified from agarose with the Magic PCR Preps DNA Purification System (Promega) digested with *Sau*3AI (Promega) and ligated into the *Bam*HI (Promega) site of the pBluescript KS+ phagemid (Stratagene). Clones containing the DNA fragment with nucleotide 1840 were identified by hybridization to ^{32}P-end-labeled primer 1. Hybridizations were performed at 45°C in 6 × SSC (SSC: 0.15 M NaCl, 15 mM sodium citrate), 1 × Denhardt's solution (0.2 g/L Ficoll, 0.2 g/L PVP, 0.2 g/L bovine serum albumin) and 0.5% sodium dodecyl sulfate overnight. The nonhybridizing probe was removed by three sequential 30-min washes at 65°C in 0.5 × SSC and 0.1% sodium dodecyl sulfate.

DNA Sequencing

The DNA was prepared from positively hybridizing colonies and sequenced by the dideoxy chain termination method (21) using double-stranded DNA as the template and a Sequenase kit (U.S. Biochemical). The DNA sequence analysis was performed using Genetics Computer Group software (22) on a VAX computer.

Results

To determine whether the R614C mutation was present in humans with MH, we amplified a 74-bp fragment of DNA containing this site. Inability of *RsaI* to cut the fragment into 43- and 31-bp fragments is indicative of a mutation in the recognition site on one of the chromosomes. In DNA heterozygous for the *RsaI* cleavage site, three products are observed after digestion: a 74-bp band representing the substituted allele and the two smaller 43- and 31-bp bands representing the normal allele (Figure 2).

We analyzed samples from 62 unrelated subjects diagnosed as MH susceptible by clinical event or contracture test, or both; 59 subjects with no previous history of MH risk; and 18 patients with intercurrent diseases who had had MH clinical episodes. Patient

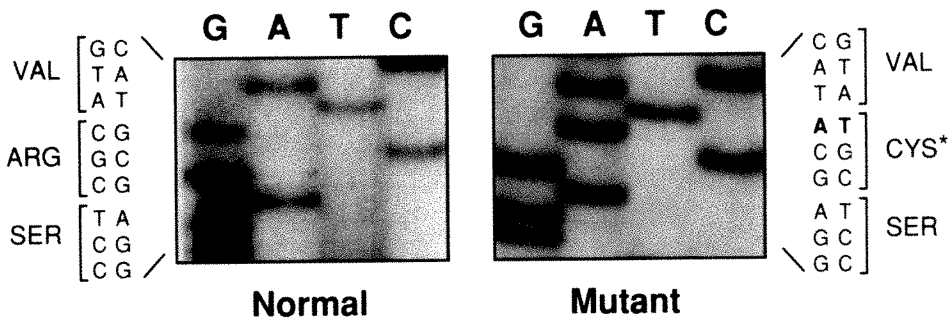

Figure 3. Autoradiogram of an RYR1 DNA sequencing gel. The sequence is from the antisense strand. The complementary sense strand is shown as is the amino acid sequence, which reads from top (amino terminus) to bottom (carboxyl terminus). The C → T substitution (*bold*) in the sense strand results in a cysteine-for-arginine substitution (*) at position 614.

III-2 (Figure 2) was the only person found to be heterozygous for the *Rsa* I site. Blood samples were obtained from this patient's close relatives, and DNA from each was analyzed for the presence of the mutation. Six additional heterozygotes were detected in three generations. No homozygotes for the alteration were found. Two of the heterozygotes (III-11, III-12) had positive contracture tests, and two (II-1, II-6) were obligate carriers. Two additional heterozygotes (IV-1, III-13) had no previous anesthetic history or contracture test but were at risk because of an affected sibling or heterozygous parent. In no instance was the presence of the substituted allele discordant with previous clinical history or laboratory investigation. All spouses tested had two copies of the normal allele. Inheritance of the MH phenotype in this pedigree on the basis of one clinical event and three positive contracture tests is compatible with a single-gene autosomal dominant mode of transmission with variable expressivity.

Subject II-3 is deceased, but six of his seven offspring (III-4 through III-9) were available for sample collection. The substituted allele was not identified in any of the six offspring or in their mother. The probability that the father had the mutation may be calculated with Baye's theorem (23) to be 1 in 31.5 (3.2%), hence it is unlikely that he inherited the mutant allele.

To confirm that the same nucleotide substitution that leads to the loss of the *Rsa*I site results in an amino acid substitution at position 614, we determined the DNA sequence from eight independent clones containing this region amplified by PCR from subject III-2. Two of the eight clones were from the substituted chromosome lacking the *Rsa*I site and with the C → T substitution at position 1840 (Figure 3). The remaining six clones from the normal chromosome had the *Rsa*I site with a C at position 1840. Therefore in this family, as in the equivalent porcine MH mutation, the C1840 → T substitution results in a substitution of a cysteine for an arginine at position 614 in the RYR1 protein.

Discussion

The major finding of this investigation is that inheritance of susceptibility to MH in 1 of 62 human pedigrees cosegregates with a substitution of cysteine for arginine in the skeletal muscle calcium release channel. The amino acid substitution arises from a C1840 → T substitution in the RYR1 gene, eliminating a recognition site for the *Rsa*I restriction enzyme. In the present family, 7 of 25 persons were heterozygous for the mutation, including three with positive contracture tests, two obligate carriers, and two persons without previous clinical history or contracture test results. Events leading to the death of the family's proband are singularly consistent with fulminant MH, and the likelihood of other clinical entities appears remote. Moreover, data from the contracture tests exceed normal cutoff points by a wide margin, supporting the correct diagnoses of the MH phenotypes in this pedigree.

The identical human mutation has recently been detected in 1 of 35 other families examined (18). The family in that report is quite small, and the clinical presentation of the proband is more indicative of masseter muscle spasm than of a convincing MH event. Furthermore, the family members were diagnosed by contracture tests that were not conducted in accord with currently accepted protocols. Under the temperature-corrected protocols used, the MH status of the proband's father was indeterminate, and the mother's results were borderline. These findings led Gillard et al. (18) to conclude that the atypical MH event and weakly positive contracture tests in their pedigree arise from a mutation that is only mildly deleterious. If the shared mutation causes MH in both families, however, little can be inferred with regard to the severity of the mutation's consequences, because in our family the event was lethal to the proband and contracture test results were well in excess of conventional normal values. Either expressivity of the R614C mutation is highly variable or differences in the details of the medical management and technical aspects of contracture testing account for the disparity. Combining data from the two investigations, 98 normal subjects failed to show the R614C mutation, suggesting that it does not exist at a high background frequency in the populations sampled and that it is unlikely that cosegregation of the mutation with MH occurs in the two families by chance alone.

Despite compelling evidence obtained by gene mapping, linkage, and mutational analysis, the causal nature of the R614C substitution in MH remains unproved. Nonetheless, abundant biochemical data support the contention that a defect intrinsic to the calcium release channel gives rise to the porcine MH phenotype. Elevations in myoplasmic calcium are observed in acute porcine MH (24) and cannot be explained by deficient activity of the calcium-adenosine triphosphatase responsible for pumping calcium from the myoplasm into the sarcoplasmic reticulum (SR) (25). Early investigations documented higher rates of calcium extrusion from porcine MH SR (10–12) through channels representing the SR constituent of the junctional triad. These channels release calcium during excitation-contraction coupling in response to T-tubule depolarization (26,27) and are modulated by calcium, magnesium, pH, adenine nucleotides (28), and acylcarnitines (29) at physiologic concentrations, as well as by a variety of pharmacologic and toxic compounds (30). Ryanodine, a plant alkaloid (31), binds to the open conformation of the channel (32), permitting the isolation and identification of the ryanodine receptor as the SR calcium release channel (RYR1) (33). Calcium release channels isolated from porcine MH muscle have an increased affinity for [^{3}H]ryanodine and an altered calcium dependency of ryanodine binding (7), defective calcium-dependent gating of single channels reconstituted in lipid bilayers (8), and distinct immunopeptide maps after digestion with trypsin (9).

In the human, Valdivia et al. (34) recently demonstrated that the MH RYR1 has a higher than normal sensitivity to calcium activation of gating and that the difference is augmented in the presence of caffeine. Hypersensitivity of the MH RYR1 to caffeine has also been found in human MH single-channel recordings (35). It is noteworthy that the calcium release channels in these investigations were isolated from persons who had not been tested for the R614C mutation or for linkage to chromosome 19 markers; hence the biochemical evidence associating human MH with altered properties of the RYR1 awaits genetic confirmation on specimens from identical sources. Despite the demonstration of biochemical abnormalities in MH tissue genotyped for the mutation, functional assays of genetically manipulated cells are required to establish the causality of the mutation. This could be achieved by expression of the normal allele transferred into phenotypically abnormal cells or by the creation of an MH-susceptible transgenic organism in a strain or species that does not exhibit MH.

The molecular events coupling sarcolemmal depolarization with changes in SR calcium permeability are poorly understood, and the manner in which a single amino acid substitution in the RYR1 molecule alters calcium gating is therefore uncertain. The RYR1 consists of 5032 amino acids with a molecular mass of 563,584 daltons (36). Approximately four-fifths of the protein comprises the cytoplasmic foot structure spanning the gap from the SR to the T-tubule sarcolemma in proximity to the dihydropyridine receptor. The functional channel is a homotetramer anchored to the SR by at least four membrane-spanning sequences at the carboxyl terminus of each molecule (36). No high-affinity calcium or nucleotide binding sites have been identified. Although glycosylation and phosphorylation sites are predicted by sequence analysis, they and the transmembrane sequences are far from amino acid 614 (36). Whether the lethal consequences of the mutation are brought forth by the loss of an essential arginine or are due to a feature of the substituted cysteine remains to be resolved. An attractive hypothesis is that the sulfhydryl group of the substituted cysteine is in an accessible and critical site for the formation of new disulfide bonds by oxidation with adjacent sulfhydryls in the MH RYR1 (37). In keeping with this premise, oxidative compounds specific for free sulfhydryl groups are known to increase SR calcium permeability, and reduction of the disulfide bonds by glutathione and other reducing agents closes the calcium release channel (38).

Even if the cysteine-for-arginine substitution is established as causal in porcine MH and a subset of human MH, important distinctions exist between the two species. Porcine MH is inherited as a recessive trait, with the homozygote manifesting the clinical episode or positive contracture test, but the mechanism of inheritance of human MH more closely fits an autosomal dominant pattern. Judging the mode of transmission in humans is not straightforward, however, because penetrance is incomplete, and expressivity is variable and dependent on exposure to an environmental factor. A difference in the apparent mode of inheritance of a trait between species does not rule out a shared molecular pathogenesis, because the identically altered gene product is expressed in a background of other gene products that may have species-specific differences under normal conditions. Variations between pigs and humans in calcium regulatory proteins other than the RYR1, such as dihydropyridine calcium channels or SR Ca^{2+}-adenosine triphosphatase, may determine whether one or two copies of a mutant RYR1 allele are required to produce the disease, as defined by the clinical event or laboratory test.

A second distinction is that all recognized porcine MH appears to derive from a common ancestor, with the cysteine-for-arginine mutation shared by all affected strains. By contrast, human MH is a much more heterogenous disorder. In humans MH has been described in families with polymorphisms linked to the RYR1 gene but without the R614C mutation (17,18) and in families in whom chromosome 19 linkage has been excluded (39). Events resembling human MH or positive contracture tests are reported in association with many other disorders, including King-Denborough syndrome (40), myotonia congentia (41), Duchenne's muscular dystrophy (42), carnitine palmitoyl transferase II deficiency (43), and central core disease. Of these, central core disease is tightly linked to the RYR1 gene (44,45), but a causative mutation has yet to be isolated. Among the many diseases that predispose to the MH syndrome in humans, only the R614C mutation appears to be shared with the disease of MH in inbred selected pig lines. Thus, the most well-studied animal analogue of MH corresponds to only a rare variant of the human syndrome. In light of this observation, the relevance of screening the potency of inhaled anesthetics, muscle relaxants, and other drugs to elicit MH in pigs before introduction into human practice must now be questioned.

We studied 18 patients with both MH and other inherited and congenital diseases. All were homozygous for the *Rsa*I recognition site at position 614 of the RYR1, underscoring the genetic heterogeneity of human MH. Many of the genes for diseases clinically associated with the human MH syndrome have been mapped to regions of the human genome not in the vicinity of the RYR1 gene. In some conditions, the association will prove to be fortuitous, with the gene carrying the MH mutation having no role in the pathogenesis of the concomitant clinical disorder. In others, the association may correspond to a single genetic defect causing both the accompanying clinical disorder and the anesthetic complication by a common pathophysiologic cascade; for example, deregulation of unbound ionized calcium in the skeletal muscle of patients with carnitine palmitoyl transferase II deficiency or Duchenne's muscular dystrophy. A mutation of any of the proteins participating in the regulation of myoplasmic calcium could potentially manifest the MH syndrome under conditions of surgical stress and anesthetic intervention.

In families in which MH-associated mutations can be identified, screening tests based on DNA analysis may be the preferred method of assigning risk. In comparison with the halothane-caffeine contracture test, mutation analysis has numerous advantages, including high efficiency and reproducibility, together with minimal cost and discomfort. Even so, clinical decision making is not trivial because the incidence of MH is unknown, and additional undetected mutations may be present. In families with identified mutations, we recommend testing all interested individuals. A positive test is evidence for MH susceptibility. Negative mutation assignment is reassuring but cannot absolutely rule out MH risk until all human MH mutations have been identified. Specific counseling with respect to risk also requires a greater understanding of the expressivity and penetrance of each mutation, as well as estimates of the new mutation rate and prevalence. Persons homozygous for the normal allele in families in which the R614C mutation is segregating are counseled to continue to avoid challenge anesthetics until these issues have been adequately addressed.

We thank J. Tomczak and L. Trani for able management of the data base; S. Ying for technical assistance; H. Rosenberg and S. Glisson for sharing contracture test data; L. Rowland and R. Pauli for insight and criticism; and the numerous family members, clinicians, and collaborators whose assistance in sample collection has made this investigation possible.

CASE REPORTS

Radiographic Examination of Catheter Position in Restricted Sacral Block After Continuous Spinal Anesthesia

Vincent W. S. Chan, MD, FRCPC, and Robert J. Smyth, MD, MSc
Department of Anaesthesia, The Toronto Hospital, Toronto Western Division, Toronto, Ontario, Canada

With increasing use of microcatheters for continuous spinal anesthesia (CSA), it has been recognized that restrictive local anesthetic spread, causing prolonged sacral/perianal anesthesia and, rarely, the cauda equina syndrome, may occur (1). Although catheter malposition and drug maldistribution are likely causes of restrictive anesthetic block, such evidence in human subjects is lacking.

We report two cases of failed CSA with use of hyperbaric lidocaine, both resulting in sacrally restricted anesthesia that was significantly prolonged but completely reversible. We also present radiographic documentation of the microcatheter position, which helps to elucidate the etiology of this anesthetic complication.

Case 1

A 73-yr-old man was admitted for transurethral resection of the prostate. He had had internal fixation of a jaw fracture years earlier under general anesthesia. He had stable angina and non-insulin-dependent diabetes mellitus that was controlled by diet. His medications included metoprolol (50 mg twice daily), enteric-coated aspirin (325 mg once a day), Septra (2 tablets twice daily), and sublingual nitroglycerin (as needed). On admission, his hemoglobin was 148 g/L, and blood glucose was 13.9 mmol/L. On physical examination, there were no findings suggestive of any neurologic disease or neuropathy, and the remainder of his investigations and physical examination were normal.

With the patient in the left lateral decubitus position, a 22-gauge spinal needle was introduced at the level of the iliac crest. The cerebrospinal fluid was slightly blood tinged but cleared rapidly, with good flow. A 28-gauge spinal catheter (Medevice Inc., Mississauga, Ontario, Canada) was threaded easily to 3 cm beyond the needle tip without paresthesia. The patient was placed in a supine horizontal position, and 75 mg of lidocaine (1.5 mL of 5% lidocaine in 7.5% dextrose) (Astra Pharma, Mississauga, Canada) was injected through the catheter over 30–45 s. After 10 min, neurologic assessment revealed only sacral and scrotal anesthesia, with normal sensation and motor function in his legs. The patient was placed in 30° head-down position, but no change in sensation or motor function was noted after an additional 10 min. The procedure was abandoned, and general anesthesia was administered (propofol, fentanyl, N_2O/O_2, isoflurane). The surgery was completed 45 min later without complication. Postoperatively, while the patient was lying supine and horizontal, radiographs of the lumbar spine were taken immediately after injection of 2.0 mL of hyperbaric contrast material (Omnipaque 240, specific gravity 1.276) (Winthrop Inc., Mississauga, Ontario, Canada) through the catheter (Figure 1). In this radiograph, dye can be seen clearly within the subarachnoid space at the level of the sacrum. Perianal sensation returned to normal within 7 h, and no bowel or bladder incontinence was noted. On follow-up 1 mo later, the patient denied any subsequent bladder or bowel dysfunction.

Case 2

A 70-yr-old man was admitted for transurethral resection of the prostate. His past medical history included an inguinal hernia repair 52 yr earlier under general anesthesia and a 15-yr history of non-insulin-dependent diabetes mellitus treated with chlorpropamide (325 mg twice daily) and glucophage (1 tablet three times a day). He also had intermittent claudication on moderate exertion. He denied any symptoms suggestive of peripheral neuropathy or neurologic disease. On admission, his hemoglobin was 155 g/L, blood glucose was 29 mmol/L, and the remainder of his laboratory tests and physical examination were unremarkable. Repeat blood glucose

levels 7 h later had declined to 17.8 mmol/L after he received 6 U of subcutaneous insulin.

With the patient in the right lateral decubitus position, a 22-gauge spinal needle was inserted at the level of the iliac crest to obtain a clear flow of cerebrospinal fluid without blood or paresthesia. A 28-gauge spinal catheter was threaded easily 2–3 cm into the subarachnoid space without paresthesia. After the catheter was secured and the patient was placed in a supine horizontal position, 75 mg of hyperbaric lidocaine (1.5 mL of 5% lidocaine in 7.5% dextrose) (Astra Pharma) was injected over a 30–45-s period. After 5 min, examination revealed no sign of motor or sensory blockade in the lower extremities despite dense anesthesia in the scrotal and perianal regions. Flushing the catheter with 3.0 mL of sterile saline solution did not produce any progression in either motor or sensory anesthesia after an additional 15 min. No further doses of lidocaine were injected. The surgical procedure was then performed under general anesthesia (propofol, alfentanil, N_2O/O_2) without complication. Postoperatively, the patient continued to describe perianal and buttock anesthesia 95 min later despite continued normal motor function and sensation in his legs. While the patient was lying supine and horizontal, radiographs of the spine were taken immediately after 2 mL of hyperbaric contrast material was injected through the spinal catheter (Figure 2). In these radiographs it is evident that the dye collection lies at the level of L3-4 within the subarachnoid space. Perianal anesthesia persisted for 4 h. After removal of the bladder catheter 2 days later, the patient did not experience any bladder incontinence. Follow-up 1 mo later confirmed no bladder or bowel incontinence.

Discussion

Recent reports of cauda equina syndrome and persistent sacral root deficits after CSA are worrisome, but these neurologic complications are probably the result of direct neurotoxic damage from repeated excessive doses of local anesthetic administered in an attempt to extend a sacrally restricted block (1,2). In these unfortunate cases, the dosages of hyperbaric lidocaine and tetracaine far exceed that which would be used in a conventional single-injection technique. To avoid the development of local anesthetic neurotoxicity, Lambert and Hurley (3) suggest restricting the amount of hyperbaric 5% lidocaine to 100 mg in establishing the initial spinal block. On the basis of the favorable neurologic outcome in our two patients, we strongly recommend that this dosage guideline be followed. Despite prolonged sacral block in both patients (4 and 7 h), the neurologic deficit was reversible, and the recovery was complete.

The frequency of catheter malposition causing sacrally restricted block in CSA is currently unknown. To determine the location of radiolucent catheters in the subarachnoid space, an injection of contrast media before radiographic examination would be necessary. Iohexol dye (Omnipaque 240) has been used safely and routinely for myelographic studies. It is highly hyperbaric (specific gravity 1.276) and presumably will deposit to the most dependent region of the subarachnoid space, similar to hyperbaric

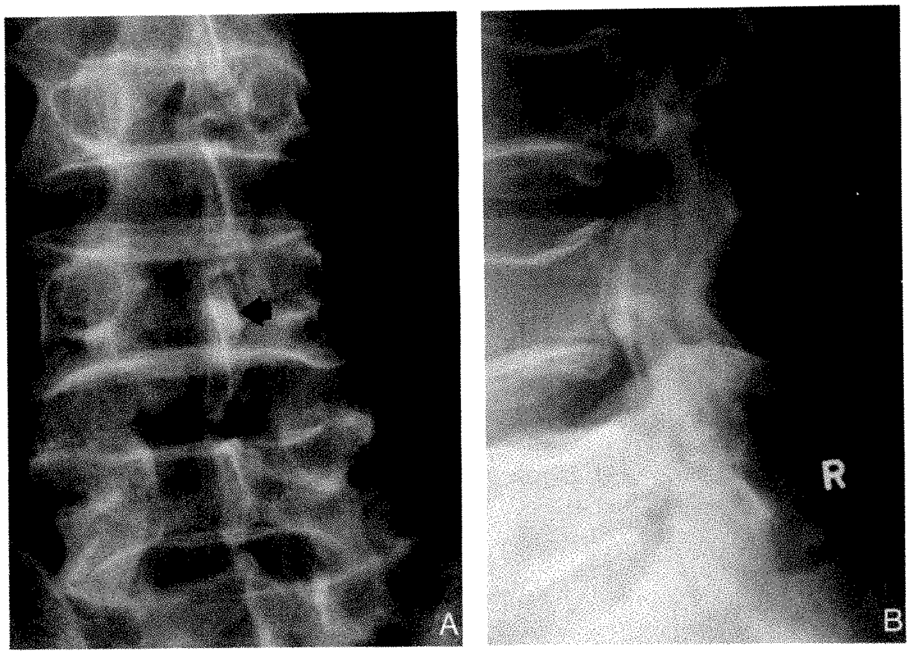

Figure 2. Anterior-posterior (**A**) and lateral (**B**) views of lumbar vertebras after injection of 2.0 mL of hyperbaric contrast material. *Arrow* indicates contrast dye collection.

lidocaine (specific gravity 1.033) but at a faster rate. Although not entirely conclusive, we believe that the dye collections seen in the anterior-posterior radiographs (Figures 1 and 2) depict the locations of the spinal catheter tips, not the gravitational pooling of the dye. In this study, radiographs taken immediately after dye injection would have kept the time of dye spreading to the absolute minimum. Furthermore, as seen in case 2, although dye and lidocaine were both injected under the same patient position condition (i.e., supine horizontal position), dye collection was found at the L3-4 level, whereas anesthetic effect was detected in the sacrum. This discrepancy in response further strengthens the notion that contrast dye was indeed highlighting the catheter tip position at the L3-4 level.

In the two cases that we have reported, although the clinical presentations are strikingly similar, the mechanism of restricted anesthetic spread in each case is distinctly different. As demonstrated radiographically, the cause of sacral anesthesia in case 1 was sacral positioning of the catheter tip. Although the insertion of the catheter was believed to be at the level of the L3-4 interspace, it is possible that the needle was introduced at the level of L4-5 and that the catheter was threaded in a caudad direction. Unfortunately, caudad deflection of the microcatheter during insertion through a straight spinal needle may occur more frequently than we realize. It is conceivable that with the use of a Sprotte spinal needle in which the lumen aperture can be oriented in a cephalad direction, or a pediatric Tuohy needle, cephalad introduction of the catheter may be enhanced. Rigler et al. (1) suggested catheter manipulation as a possible solution to correct restrictive anesthetic spread. We found that in the absence of radiographic documentation, it is impossible to determine the catheter tip position or the proper distance to pull back. Furthermore, manipulation of the catheter after stylet removal can be exceedingly difficult, owing to the small caliber and stretching of the catheter itself.

We believe that case 2 exemplifies the phenomenon of drug maldistribution in the presence of a properly placed spinal catheter. Despite the catheter tip at the L3-4 level, sacral anesthesia still occurred. This finding is in agreement with the spinal canal model data that showed that hyperbaric lidocaine preferentially pooled in the distal dependent (sacral) end of the glass tube when it was injected through a microcatheter at a level equivalent to L3-4 (3,4). In clinical practice, whether the use of a "lighter" local anesthetic solution (isobaric or hypobaric) will enhance a more uniform distribution, as demonstrated experimentally, has yet to be verified. Rigler and Drasner (4) also showed experimentally that rapid subarachnoid injection (<30 s) is another critical factor in improving distribution. Unfortunately, it is our clinical impression that manual injection of 1 mL with a tuberculin syringe through a 28-gauge catheter in <30 s is exceedingly difficult to achieve. To reach a faster injection rate (<5 s), it is necessary to use a larger caliber catheter (e.g., 20 gauge), which may still result in maldistribution and more likely a higher incidence of postdural puncture headache (5).

We were unsuccessful in promoting cephalad spread of hyperbaric lidocaine by either placing the patient in a 30° head-down position (case 1) or flushing the catheter with sterile saline solution (case 2). It is unlikely that head-down tilting after the establishment of sacral anesthesia would have a significant effect; however, this maneuver may prove beneficial before further injections. Conceptually, catheter flushing with several milliliters of saline solution may help to dilute the localized anesthetic, but we found that this maneuver still failed to promote cephalad spread.

In summary, we have presented two cases of failed continuous spinal anesthesia. Although the mechanism of restricted local anesthetic distribution in each case was distinctly different, they cannot be distinguished on clinical grounds. By limiting the maximal amount and concentration of local anesthetic used, and by accepting when the CSA has failed, it is likely that serious neurologic complications can be prevented. Future clinical studies to document the causes of CSA failure (catheter malposition versus drug maldistribution) and their frequency of occurrence would be of clinical importance.

Patient-Controlled Spinal Analgesia for Postoperative Pain Control

Marc Domsky, DO, and David Tarantino, MD

Department of Anesthesiology, Maryland Institute for Emergency Medical Services Systems, Baltimore, Maryland

With continuous spinal anesthesia, maintaining the catheter for postoperative analgesia can be a natural extension of its intraoperative use. The use of a continuous intrathecal catheter for patient-controlled analgesia (PCA) has not been reported. We report a case of patient-controlled spinal analgesia with fentanyl.

Case Report

A 70-yr-old woman (111 kg, 157 cm) presented with a comminuted subtrochanteric fracture of the right hip. Her medical history included chronic obstructive pulmonary disease, deep venous thrombosis of both lower extremities, and peripheral vascular disease; medications included lorazepam and furosemide. The scheduled procedure was a right femoral intramedullary nailing with a Russell-Taylor Recon nail and cerclage wiring.

With the patient in the left lateral decubitus position, a 17-gauge Tuohy needle was placed at the L2-3 interspace, and a 18-gauge catheter (Perifix, Burron, Bethlehem, Pa.) was inserted 3 cm into the subarachnoid space; no paresthesias were elicited during placement. A millipore filter was connected to the catheter. The patient was turned to the supine position, and a total of 50 mg of 5% lidocaine with 7.5% glucose was injected incrementally over 15 min, resulting in a sensory blockade to T-10. The patient was then repositioned supine on a fracture table by the surgeons. Another 50 mg of lidocaine and 12.5 μg of preservative-free fentanyl was injected incrementally through the intrathecal catheter 1 h later, just before making the surgical incision. During the 4.5-h procedure, an additional 150 mg of lidocaine in divided doses was administered through the catheter to maintain a sensory blockade to T-10. The patient was maintained in the horizontal position throughout all injections and for the duration of the procedure. A total of 6 mg of midazolam and 150 μg of fentanyl was administered intravenously throughout the procedure for sedation in support of the spinal anesthetic.

The patient was moving her legs on arrival in the recovery room and complained of pain within 10 min. Her level of sensory blockade was to L-3. Analgesia was evaluated by a visual analogue scale (VAS) in which 10 cm indicated maximal pain and 0 cm complete pain relief. This patient's pain score was 10. After injection of 12.5 μg of fentanyl through the catheter, her score decreased to 5 within 15 min. A PCA pump (Pancretec, Provider 5500, San Diego, Calif.) with a reservoir of fentanyl in preservative-free normal saline solution (2 μg/mL [250 mL]) was connected to the catheter. Initial settings were for a 3-mL (6 μg) bolus dose with a lockout interval of 1.5 h. After the patient was instructed in the use of PCA, she was discharged to the stepdown unit with a VAS score of 5, feeling comfortable. Vital signs were monitored every 2 h. The VAS score and level of consciousness were documented every 8 h.

Over the next 12 h, 24 mL (48 μg) of fentanyl was used. The patient made a total of 33 requests, 8 of which were delivered. Her VAS score remained 5. The lockout interval was decreased to 1 h. During the next 24 h, 21 mL (42 μg) of fentanyl was used in seven doses (the patient made nine requests). Her VAS score ranged from 3 to 5. In the final 24-h period of catheter use, the patient's activity was increased, and she was moved to a chair twice during the day. Fentanyl (33 mL [66 μg]) was administered on 11 occasions (in response to 21 requests). Her VAS score ranged from 1 to 3. Indomethacin and oxycodone with acetaminophen were administered orally. The catheter was removed without difficulty; the tip was sent for culture, and results were negative. The patient never experienced any signs of postdural puncture headache, nausea, pruritus, respiratory depression, or somnolence. She was discharged on the seventh postoperative day, pleased with her treatment.

Discussion

Renewed interest in continuous spinal anesthesia because of the availability of small-bore spinal catheters has led to a number of reports describing its advantages over both single-dose spinal and continuous epidural anesthesia, but few reports describe the catheter's use for postoperative analgesia (1–4). If there are benefits for anesthesia, should there not be benefits for analgesia? Experience with both intrathecal narcotics and PCA led to our combined approach for this patient's postoperative pain management.

A recent study evaluating continuous intrathecal lidocaine infusions for postoperative analgesia found them extremely effective (5); yet other reports suggest that maldistribution and a relatively high dose of local anesthetic may lead to neurotoxicity (6,7). Therefore, we elected to use opioids alone. The high lipid solubility of fentanyl allows for rapid onset of analgesia and limited rostral spread. This results in minimal respiratory depression and a short duration of effective analgesia (3–4 h). Patient-controlled analgesia adds a psychologic advantage to postoperative pain management (8). The interval between the onset of pain and delivery of analgesic medication is minimized, and the measure of patients' control over their own problem undoubtedly plays a significant role in overall comfort and satisfaction.

The most serious potential complications associated with this technique include subarachnoid infection, postdural puncture headache, and respiratory depression. Although the incidence of infection should be no different than for a continuous epidural catheter, the sequelae of meningitis may be far greater. Recent studies suggest, however, that colonization and subsequent central nervous system infection should not be a commonly encountered problem (9,10). Postdural puncture headache remains a controversial issue. Denny et al. (11) recently reported the incidence of postdural puncture headache to be 1.1% among a patient population with a mean age of 63 yr (18-gauge Hustaud needle, 20-gauge catheter). Others have shown a postdural puncture headache rate of 4% and 13% with various sizes of needles and catheters (1,12). Of note, the mean age of patients in these studies was significantly less than 63 yr. Suffice it to say that the smallest catheter available should be used in the youngest patients. Respiratory depression should be limited if vigilant patient assessment is performed hourly and optimal therapy is established. The most common problems with PCA therapy are related to operator errors, not the drug or the pump (13). This patient was sent to the stepdown unit postoperatively only because of the duration of her procedure and her overall medical condition. Ready (14) clearly showed that with extensive nursing education, hourly observation for sedation and ventilatory rate, protocols for immediate treatment of complications, and immediate availability of medical personnel, patients can be cared for on conventional hospital wards without special monitors.

Recently, Glass et al. (15) used a PCA pump to establish the efficacy of epidural versus intravenous administration of fentanyl. They found that once equieffective analgesia was obtained, both fentanyl utilization and plasma concentrations were similar between the two routes of administration. They suggest that there is little advantage to the epidural administration of fentanyl, because its high lipid solubility leads to rapid systemic absorption. The mean hourly cumulative dose of fentanyl in this 12-h study was 52.1 μg (VAS 2–4). During the first 12 postoperative hours, our patient used a total of 60 μg and thereafter approximately 2 μg/h of fentanyl for the next 24 h (VAS 3–5). Perhaps intrathecal administration of fentanyl will prove to be more efficacious than either epidural or intravenous infusions, because substantially lower dosages of fentanyl may be required to achieve adequate analgesia.

Ideal therapy for postoperative analgesia should provide rapid onset of analgesia, easy control, limited tolerance, and few or no side effects. Further investigation of patient-controlled spinal analgesia with fentanyl is necessary to define its role as another modality for postoperative pain management.

A Rare Case of Perineal Pain: Intestinal Perforation Caused by a Press-Through Package

Shigehito Sato, MD, Takuo Endo, MD, Keiichi Tajima, MD, and Yoshihiro Sanada, MD
Divisions of Anesthesiology and Surgery, Tsuchiura Kyodo Hospital, Tsuchiura-City, Japan

Patients with advanced rectal cancer sometimes complain of perineal or pelvic pain, or both (1,2). One patient who had undergone surgery for rectal cancer 10 yr earlier visited our pain clinic complaining of perineal pain. We assumed that the pain was due to a local invasion of recurrent cancer, and caudal blocks were performed. A laparotomy was performed because a vesicointestinal fistula was suspected during the pain management. A press-through package (PTP) was found within a mass of abscess in the pelvic cavity, with one portion of the intestine perforated. After the laparotomy, the patient was discharged and was pain free. A case of fatal fecal peritonitis resulting from colon perforation caused by plastic sheeting has been reported (3). We present a rare case of perineal pain caused by intestinal perforation that had occurred 12 mo earlier after the accidental ingestion of a PTP.

Case Report

A 50-yr-old woman of normal intelligence who had undergone a low anterior resection with end-to-end anastomosis for rectal cancer 10 yr before complained of sudden lower abdominal pain. She had also had an uneventful cholecystectomy for acute cholecystitis 3 mo earlier.

The patient underwent many examinations without detection of abnormal findings, and after treatment with oral analgesics, the abdominal pain decreased gradually, except for persistent perineal pain. Because the pain was continuous and unresponsive to analgesics, we suspected that it was due to local recurrence of the patient's rectal cancer, although there was no evidence to support this.

The patient reported to our pain clinic 11 mo after the appearance of the sudden lower abdominal pain. Because she complained of perineal pain only, a caudal block with 10 mL of 0.25% bupivacaine was performed. She complained of feeling pressure at the caudal region during the injection of anesthetics. Moreover, the pain did not disappear after the block. Caudal blocks were performed five times every other day with no improvement over the first block.

With the sixth caudal block, we aspirated purulent discharge through a block needle. We administered antibiotics locally and orally, suspecting that the infection was caused by our needle. Two days later, her urine was a muddy yellow and smelled of stool. The patient was referred to the surgery department because of a suspected vesicointestinal fistula. After detailed examinations by urologists, gynecologists, and surgeons, a laparotomy was performed because a recurrence of rectal cancer was suspected.

During the procedures for detaching the adhered intestines, a purulent discharge appeared from a space between the urinary bladder and uterus. The abscess occupied a space created by the cystic bladder as the frontal wall, the uterus as the posterior wall, and a lump of adhered small intestines as the upper wall. After the abscess was drained, a PTP containing an intact tablet was found (Figure 1), and a perforated portion of small intestine was confirmed. Anastomosis between the small intestines was performed; however, the vesical fistula did not need a surgical closure. The patient's complaints disappeared postoperatively, and she was discharged 2 wk after the operation.

She could not remember when she took the tablet embedded in the PTP, but she mentioned that she might have taken it along with other drugs in the darkness of a bedroom at night several weeks before the sudden onset of the abdominal pain.

Discussion

Intestinal obstruction resulting from ingested foreign objects is common, but perforation is rare (4). Button battery ingestion in infants and children has been reported, but these objects are usually safe (5). Surgical sponges retained postoperatively do not cause a

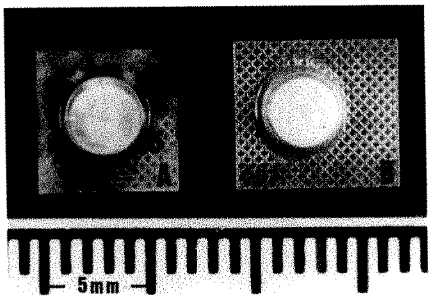

Figure 1. **(A)** A press-through package with an intact tablet found in an intestinal abscess. **(B)** An identical, new tablet embedded in a PTP.

significant problem, except in rare cases of related abscess (6,7). Considering the type of operation previously performed in this patient for rectal cancer, there would be no cause-effect relation between the operation and colon perforation. Severe cases of intestinal perforation resulting from ingested fish bones (8) and a chicken bone (4) have been reported. In the latter case, an ingested chicken bone perforated the colon. Only one fatal case of intestinal perforation after ingestion of plastic sheeting from a PTP has been reported (3). This case, involving a mentally retarded patient, showed severe fecal peritonitis, and a PTP was found by autopsy.

A PTP consists of a dome of vinyl chloride and a thin aluminum lid. Because this container is very easy to separate and carry, many drugs are packaged in this way; however, after a PTP is separated, each corner has sharp edges. If ingested accidentally, it becomes a dangerous foreign body. Moreover, PTPs are unfortunately radiolucent, so their presence cannot be confirmed by radiographic examination. A nondiagnosed radiolucent plastic coin that remained impacted for 11 mo in the esophageal wall of a child was reported (9). In our patient, approximately 12 mo passed before the PTP was discovered.

We believe that the internal pressure in the patient's abscess was high and that the purulent discharge flowed out from the closed space of the abscess during laparotomy. Moreover, a vesical fistula between the abscess occurred 2 days after aspiration of the purulent discharge. When the purulent discharge was aspirated from the caudal space, we thought that the infection was caused by the caudal blocks. Because the caudal space was anatomically close to the intraabdominal abscess, we believed that the infection in the caudal space was due to spread from the abdominal abscess through coarse tissues within the sacral foramina. The complaint by the patient of pressure during caudal block may also support this possibility.

In summary, we present a rare case of perineal pain caused by ingestion of a PTP. Ingestions of PTPs are almost always due to patient carelessness, although a case of mental retardation has been reported (3). In our pain clinic, we sometimes prescribe drugs for episodes of pain. It is therefore possible that the accidental ingestion of a PTP may occur because of impatience experienced by the patient during severe pain. In our medical practice, we need to ensure that there is sufficient workup before the treatment of chronic pain, and if repeated blocks are unsuccessful, another etiology, such as ingestion of a radiolucent foreign body, should be suspected as a possible cause of chronic perineal pain.

Superior Laryngeal Nerve Block as a Supplement to Total Intravenous Anesthesia for Rigid Laser Bronchoscopy in a Patient With Myasthenic Syndrome

Lewis A. Hunt, MD, and Gwendolyn L. Boyd, MD

Department of Anesthesiology, University of Alabama at Birmingham, Birmingham, Alabama

---

Myasthenic syndrome, also known as Eaton-Lambert or Lambert-Eaton syndrome, is typically characterized by proximal limb muscle weakness. Patients with myasthenic syndrome demonstrate an increased sensitivity to all muscle relaxants, resulting in unpredictably prolonged weakness that may persist for many days. The response to anticholinesterase drugs in these patients is poor (1).

This report describes the use of superior laryngeal nerve block as a supplement to total intravenous anesthesia for rigid laser bronchoscopy to avoid muscle relaxants in a patient with myasthenic syndrome. This anesthetic technique has not been previously reported in the patient for whom muscle relaxants are relatively contraindicated.

Case Report

A 69-yr-old woman, weighing 73 kg, with myasthenic syndrome was scheduled for rigid laryngoscopy and bronchoscopy for subglottic stenosis. The diagnosis of myasthenic syndrome was made 7 mo earlier when she developed respiratory failure, requiring mechanical ventilation for 59 days. A tracheotomy was performed at that time. A thorough examination revealed no evidence of malignancy, although she had required mechanical ventilation for 5 days after a routine cholecystectomy several years earlier. Her trachea was eventually extubated, and she was discharged.

The patient presented 5 mo after discharge with a 1-wk history of dyspnea and a tingling sensation in her arms, legs, and trunk. Physical examination revealed no significant change in muscle strength from her previous clinic visits. Admission medications included prednisone (60 mg/day) and a thiazide diuretic for hypertension. Arterial blood gases on admission were pHa 7.45, $Paco_2$ 45 mm Hg, Pao_2 79 mm Hg, with an inspired O_2 concentration of 0.21. Initial forced vital capacity was 1.15 L. Airway films revealed tracheal stenosis at the level of the previous tracheotomy site. She was evaluated by the otolaryngology service and scheduled for CO_2 laser ablation of the stenotic lesion.

The patient was orally premedicated with famotidine (20 mg) and metoclopramide (10 mg). After breathing oxygen, anesthesia was induced with propofol (2 mg/kg IV), followed by assisted and then controlled ventilation through a mask with 1.25% expired isoflurane for 10 min. Bilateral superior laryngeal nerve blocks were performed with 3 mL of 2% lidocaine. Direct laryngoscopy was performed without difficulty. A 6.0-mm Rusch red rubber endotracheal tube wrapped with foil tape was used for intubation. The cuff was inflated with sterile normal saline solution. Anesthesia was initially maintained with isoflurane.

Direct laryngoscopy by the otolaryngologist revealed no significant laryngeal abnormalities. The endotracheal tube was then removed and a rigid bronchoscope introduced. Satisfactory ventilation was achieved with a Sanders jet ventilator through the rigid bronchoscope with an initial inspired O_2 concentration of 1.0. Isoflurane was discontinued, and a propofol infusion was started at 150 $\mu g \cdot kg^{-1} \cdot min^{-1}$.

A small area of stenosis was noted 3 cm inferior to the glottis. This area was ablated with the CO_2 laser. Just before and during each use of the laser, the inspired O_2 concentration was decreased to 0.21 by dilution with air through an air-oxygen blender.

The rigid bronchoscope was removed. Ventilation was then controlled by a mask for 10 min as satisfactory spontaneous respiration resumed. Acceptable hemodynamic control was achieved with this anesthetic technique. The patient's systolic arterial pres-

sure was maintained within 30% of the preoperative baseline blood pressure, and her heart rate ranged from 60 to 80 beats/min. She was taken to the postanesthesia care unit in good condition and was discharged 2 days later with no stridor or complaints of dyspnea. No muscle relaxants were administered, and a stationary field was maintained throughout the procedure.

Discussion

Myasthenic syndrome is a disorder of neuromuscular transmission involving the presynaptic membrane. The etiology is thought to involve the development of IgG antibodies to voltage-gated calcium channels on the presynaptic membrane, inhibiting calcium flux, and thereby blocking acetylcholine release (2). The antibodies cross-react with the calcium channels on the surface of neural crest tumors, including small-cell lung carcinoma. Associated malignant tumors are seen in 72% of men and 32% of women patients with myasthenic syndrome (3). There may be improvement when tumors are removed.

The clinical features of myasthenic syndrome include proximal limb muscle weakness, myalgias, urinary retention, constipation, dry mouth, and impotence. In contrast to myasthenia gravis, the weakness typically affects the lower extremities, fluctuates in severity, and improves with exercise (1,3). In addition, ocular, bulbar, and respiratory muscle involvement are rare in myasthenic syndrome.

The diagnosis is confirmed by electromyography (EMG), which reveals a decremental response at low rates of stimulation and a marked incremental response at high rates of stimulation (3). Tetanic stimulation results in a progressive increase in muscle strength. Posttetanic potentiation is marked (1). The motor unit potential is small and of short duration. The electromyogram in myasthenia gravis reveals a decremental response to stimulation with a normal motor unit potential.

Anticholinesterases such as pyridostigmine have been used to improve neuromuscular transmission but are relatively ineffective in patients with myasthenic syndrome. Guanidine increases the duration of the action potential, but its use is limited by its marked bone marrow, renal, and hepatic toxicity. 4-Aminopyridine and its less central nervous system-toxic derivative 3,4-aminopyridine block voltage-dependent potassium conduction, prolonging depolarization and thereby enhancing voltage-dependent calcium influx, with resultant increases in quantal release of acetylcholine. Although it has limited availability, 3,4-aminopyridine in a double-blind, placebo-controlled study resulted in improvement in all patients with myasthenic syndrome with little toxicity (3,4). Recently, 3,4-aminopyridine was administered postoperatively to a patient with myasthenic syndrome who had been taking it preoperatively and who had an ineffective reversal of vecuronium with neostigmine. Prompt return of neuromuscular function ensued (4).

Chronic immunosuppression has been described as the most effective therapy for long-term symptom control. Although complete remission is rare, some clinical improvement has been observed with corticosteroids, azathioprine, and plasmapheresis (3,4).

Patients with myasthenic syndrome present a challenge to the anesthesiologist because of their extreme sensitivity to muscle relaxants and the potential for prolonged weakness for many days postoperatively.

Inhaled anesthetics have been recommended when muscle relaxation is required. If this is not satisfactory, short-acting muscle relaxants in small incremental doses can be used when anticipating prolonged postoperative residual neuromuscular blockade. A neuromuscular blockade monitor should be used to assist in the incremental dosing of muscle relaxant. Nondepolarizing agents should be reversed as usual at the conclusion of the procedure; however, patients with myasthenic syndrome respond poorly to anticholinesterases (1).

Upper airway lesions are often treated with laser bronchoscopy. A stationary field is mandatory to avoid injury to the surrounding tissues. General anesthesia is the preferred method for laser bronchoscopy. However, inhaled anesthetics have the significant disadvantage of producing operating room pollution when scavenging capability is limited, such as during rigid bronchoscopy. Nitrous oxide should be avoided because of its propensity to support combustion (5). Total intravenous anesthesia avoids these problems. In most patients, muscle relaxants are used concomitantly, because propofol alone, even in high doses, provides inadequate intubating conditions for most patients (6).

Superior laryngeal nerve blocks provide anesthesia to the epiglottis, aryepiglottic folds, and laryngeal structures to the false cords. Contraindications to superior laryngeal nerve block include coagulopathy, full stomach, and local pathology. Superior laryngeal nerve block was recently shown to attenuate the hemodynamic and catecholamine release associated with laryngoscopy in a group of patients undergoing coronary artery bypass grafting (7).

Should inadequate conditions for bronchoscopy have resulted, the alternative plan was to administer small, incremental doses of an intermediate-duration nondepolarizing muscle relaxant, maintaining at least 10% twitch height, if possible. At the conclusion of the procedure, an anticholinesterase agent would be administered to reverse the muscle relaxant. Muscle relaxants have been successfully reversed without difficulty in patients with myasthenia gravis with maintenance of 10% twitch height by giving approximately 10% of the usual dose of pancuronium (8). Despite the marked dissimilarities of the two diseases, it was hoped that muscle relaxants would be as reversible in this patient with myasthenic syndrome as in normal patients with a twitch height of 10% before reversal (9). However, the anesthetic literature refers to the ineffectiveness of anticholinesterases and the unpredictability of prolonged duration of muscle relaxants in myasthenic syndrome (1,2,4). 3,4-Aminopyridine was not available to us should reversal with anticholinesterase have been inadequate.

In this particular case, it was feared that the administration of muscle relaxants could produce profound weakness, necessitating prolonged mechanical ventilatory support that would result in further exacerbation of her tracheal stenosis. The patient's extreme sensitivity to muscle relaxants had already been demonstrated several years earlier, when she required mechanical ventilation for 5 days following a cholecystectomy after having been given pancuronium.

Thus, muscle relaxants were relatively contraindicated in this patient; however, a stationary surgical field was mandatory to avoid laser injury to surrounding tissues. An inhaled anesthetic was not feasible because the patient was jet ventilated through the rigid bronchoscope. Prompt extubation after laser bronchoscopy decreases the likelihood of recurrent tracheal stenosis.

In summary, the use of superior laryngeal nerve block and total intravenous anesthesia provided a number of advantages during laser bronchoscopy: (a) facilitation of intubation and bronchoscopy in a patient who had not received neuromuscular relaxants; (b) neuromuscular relaxation of the upper airway, and (c) decreased anesthetic requirements. This technique may prove useful for patients with other disease entities in which muscle relaxants are relatively contraindicated.

Letters to the Editor

Difficult Endotracheal Intubation

To the Editor:

I read with great interest the letter to the editor by Benson (1). The use of a gum-elastic bougie for difficult intubation seems to have been practiced in the United Kingdom since its introduction in 1949 (2) and as a first choice when the cords cannot easily be seen at laryngoscopy at Cardiff (3), but this is not so in the United States. We have developed an alternative device for difficult intubation when only the epiglottis is visible at laryngoscopy: a J-, hockey-stick-, or golf-club-shaped endotracheal tube (ETT) which is shaped by immersion in iced water (4).

In practice, when the tip of the epiglottis comes into view on laryngoscopy, the epiglottis is lifted with the tip of the ETT which is then guided beneath the inferior surface until the glottis is passed. During this maneuver, an assistant maintains gentle backward pressure on the cricoid cartilage to prevent esophageal intubation. The assistant also presses on the area of the neck that provides the best view of the epiglottis. As the tip of the ETT gradually softens at room and body temperatures, the tube is advanced while the angle becomes less acute and more easily enters the trachea. Simultaneously, the assistant confirms passage through the glottis by tactile sensation. Insufflation of oxygen can be carried out as intubation proceeds. In an awake patient, elicitation of persistent cough indicates successful intubation. In an anesthetized patient, when the tip of the ETT is located at the glottis, ventilation can be accomplished by an assistant as intubation progresses. A stylet cannot be used with this method as it might not easily be removed owing to the angle of the ETT tip. Armored ETTs made of silicon rubber cannot be used for this technique, but a Mallinckrodt reinforced polyvinylchloride ETT (Glens Falls, N.Y.) can be used. For more than 25 yr, we have not been obliged to use fiberoptic bronchoscopy, a light wand, a stylet, or a gum-elastic bougie for endotracheal intubation when the epiglottis is visible at laryngoscopy.

Should the Anesthesiologist Estimate the Patient's Weight?

To the Editor:

Anesthesiologists are frequently called upon to anesthetize a patient without an accurate measurement of the patient's weight. Because the appropriate dose for many drugs administered during anesthesia is weight dependent, we frequently either ask the patient to estimate his or her own weight, or we estimate it ourselves. No information is available to tell us which estimate is most accurate, or indeed if either estimate is accurate.

After obtaining institutional approval and patient consent, we studied the weights of patients presenting to our ambulatory surgery clinic. Four resident anesthesiologists and 174 patients participated in the study. The anesthesiologist first estimated the patient's weight, then asked the patient for an estimation of weight, and then finally measured the patient's weight.

We found that the residents' estimation deviated from the patient's actual weight by an average of 8% ± 10% (standard deviation), and that the patients' estimation deviated from their own weight by an average of 4% ± 4% (standard deviation). While it is probable that neither average deviation is clinically significant, the spread of the estimates may be clinically significant. The patient's estimation of weight (range 16.7% under to 11.5% over) was more likely to be close to the actual weight than the anesthesiologist's estimation (range 52.6% under to 18.6% over).

We have concluded that, for any given patient, the anesthesiologist's estimation and the patient's estimation of patient weight may be significantly incorrect. However, the patient estimation is likely to be closer to the actual weight.

Ralph Waters' Ghost and the AUA

To the Editor:

We read with great interest Dr. Papper's description of the formation of the Association of University Anesthesiologists (AUA) (1). It is rare to have one of the major protagonists comment on events 30 yr later. Yet, this type of paper is important for it demonstrates the necessity of having documents enhanced by the memory of those involved. Often in historical assays this combination is not possible.

Without the foundation in academic anesthesiology provided by Ralph Waters and his disciples, however, it is questionable whether the AUA would have had sufficient strength to form. Of the four original founding members, only Beecher was trained outside of Waters' influence. Of the founding 37 members, 22 (59.9%) were trained within the Waters' sphere (L. E. Morris. The Waters' Tree. Unpublished). Beecher and his group totaled seven members (18.9%), and Lundy's legacy was three members (8.1%). The remaining five (15.5%) of the founders were trained at various locations in the United States and Canada (2).

The requirement that candidates of the American Board of Anesthesiology (ABA) be members of the American Medical Association (AMA) and the American Society of Anesthesiologists (ASA) was "left over" from the original quest for specialty status for anesthesiologists. The New York Society of Anesthetists, which in 1936 became the ASA, created a new class of membership called "Fellows" for the expressed purpose of delineating specialists. Rigid adherence to AMA guidelines allowed the fellowship requirements to ostensibly become those of the ABA when the Board was formed 1938. Owing to the small number of physicians specializing in anesthesia in the late 1930s, it was necessary to enlist the aid of more powerful, established organizations such as the AMA to ensure that diplomates of the Board were recognized as practicing a medical specialty (3). Consequently, to win AMA approval, one of the requirements was AMA membership.

Finally, it is interesting to note that Waters and Rovenstine shared differing views with respect to the political establishment of organized anesthesia. As Waters wrote to Rovenstine in 1935, "You do not realize it but every single thing you or I do . . . tends to antagonize the old wheel horses of the anesthesia organizations" (4). Waters felt that the establishment of teaching within university centers was one way in which anesthesiology would continue to develop. That the AUA exists is also a credit, however indirect, to the vision of Ralph Waters.

In Response:

I am pleased that these two able anesthesiologists, Drs. Bacon and Lema, thought that my article describing the beginnings of the Association of University Anesthesiologists was of great interest and also, in their opinion, important.

All of us who are descended intellectually and professionally from Ralph Waters are very proud of our heritage and enjoy the recognition that it confers on us. Of the founding four members, I had the additional unique privilege of being a resident of Dr. E. A. Rovenstine who was Dr. Water's first and probably most distinguished disciple. The issue, however, of our anesthetic origins, while important, was not viewed by the Founding Four as crucial to AUA. We felt, and I still think correctly so, that University Anesthesiology should comprise all the academically talented people regardless of their origins—and in my own opinion—irrespective of those origins.

The discussion that Drs. Bacon and Lema provide about the relationships of the American Board of Anesthesiology and the American Medical Association do not seem to me to explain the problems we encountered in the earliest days of the AUA. They are certainly of interest and I'm sure that those concerned with the history of organized medicine and specialities will find that information of value to them.

Finally, I think it is necessary to state that the hard work of a small group of individuals, as we were then, depended heavily upon our productivity rather than our professional ancestry. If I had to guess, I would think that Dr. Waters would have been very supportive and proud of the AUA as the manifestation of academic youth and vigor in the field to which he contributed so much.

Although it appears only tangentially in my original article, I can assure Drs. Bacon and Lema that Emery Rovenstine was very supportive of what we were doing and was very pleased that we wanted him to be one of the first elected members. He told me many times that new paths must be found to address new problems. He understood then, as I believe I understand now, that without change there is no progress. However, change, per se, does not identify automatically with progress. That is why continuous and evolving brilliant leadership is necessary to make our specialty the living and dynamic organism that it can be.

No ghost is required with those attitudes. The freedom of descendants to be original in no way vitiates the affection and respect all of us have for Ralph Waters—the man who made most of us possible and is permanently enshrined in the pantheon of the anesthetic gods. The Ralph M. Waters Award that I was privileged to receive is among my most cherished possessions.

Suicide Attempt After Anesthesia

To the Editor:

A 58-yr-old man was admitted to a municipal hospital for an inguinal herniorraphy. He was otherwise healthy and was taking no medications. He had a negative medical and psychiatric history but was described as being excessively talkative, and the resident who took the history believed that the patient might be having paranoid delusions. Although a psychiatric consultation was requested, it was not carried out before the surgical procedure. The patient received general anesthesia (isoflurane, nitrous oxide, midazolam, fentanyl, thiopental, and atracurium) and had the hernia repaired. He had an uneventful recovery in the postanesthesia care unit, and there were no reports of unusual behavior. Several hours later, after the patient had been discharged to the ward, he was found on his bed with a deep bleeding wound across the neck. He was taken to the operating room, the neck was explored, and the hemorrhage was brought under control. He later admitted that he had tried to kill himself with a razor blade and was diagnosed as suffering from schizophrenia.

Many factors surrounding anesthesia and surgery may trigger emergence delirium and postoperative psychosis. These include drugs, fever, pain, hypoxia, metabolic derangements, and psychological factors (1). This patient was already suffering from an undiagnosed psychiatric disorder that made the initial differential diagnosis somewhat difficult.

The incidence of schizophrenia is much higher in the lower socioeconomic groups (2). Given the fact that municipal hospitals tend to serve this patient population, a high index of suspicion should be maintained in this setting. An elective preoperative psychiatric evaluation may be warranted in a patient suspected of suffering from a mental illness. This will not only help with the differential diagnosis of postoperative psychosis, but may also and most importantly, prevent the patient from harming himself or others.

How Does Epidural Anesthesia and Analgesia Influence Perioperative Coagulability?

To the Editor:

We read with great interest the editorial by Steele and colleagues (1) accompanying the paper by Tuman et al. (2). We would like to commend Steele et al. for their review of the current literature regarding the influence of epidural anesthesia and analgesia (EAA) on perioperative coagulability. Tuman et al. have put forth an outstanding effort that helps better differentiate why those of us performing general anesthetics with epidural catheters placed for postoperative pain control believe that this is superior to the more traditional approach of general anesthetics with on-demand postoperative analgesics (intermittent intramuscular, intravenous, or oral pain medications).

Anesthesiologists have discovered that appropriate management of perioperative hemodynamic abnormalities can influence outcome in "high-risk" patients, although stable perioperative hemodynamics do not necessarily ensure uneventful cardiovascular outcome. Tuman has put forth an interesting proposal of "perioperative hypercoagulability" as another issue that must be dealt with in "high-risk" patients. How blockade of the "perioperative stress response" may influence this propensity for hypercoagulability in the postoperative period is still not well understood.

We would like to qualify and expound upon one idea put forth in the editorial by Steele et al. stating: "Fibrinogen, a glycoprotein essential to hemostasis and blood viscosity, is frequently increased in patients with vascular disease. Perhaps EAA reduces fibrinogen." It is important to remember that the half-life of fibrinogen in humans is 3–4 days and in Tuman's study the average utilization of epidural catheters was 2.4 ± 0.98 days. Speculation that this intervention, administered for such a period of time, would influence fibrinogen levels significantly in the postoperative period must take the long half-life into account. It might be that augmented fibrinogen production is reduced by EAA, although this will be difficult to prove in clinical studies owing to the large variability involved in performing functional fibrinogen assays.

Fibrinogen plays an essential role in hemostasis and the maintenance of blood viscosity. It mediates the formation of platelet aggregates and, in the coagulation cascade, is transformed by thrombin into fibrin monomers that polymerize to form the basis of a hemostatic plug. Ten to twenty-five percent of the total body fibrinogen is extravascular. Of the circulating fibrinogen in blood, about 3% is located in the platelet alpha granules, although it is unclear if this is the result of fibrinogen biosynthesis by megakaryocytes or due to platelet uptake from the plasma. Plasma levels of fibrinogen and a subset of other hepatic proteins increase during the "acute-phase response" to injury and infection (3). For fibrinogen, the protein level reflects a coordinated increase in the hepatic production of the mRNAs that direct the synthesis of the three pairs of nonidentical polypeptide chains that compose fibrinogen. The increase is predominantly in response to interleukin-6 (IL-6) produced by monocytes/macrophages. Interleukin-6, a key mediator in the inflammatory response, preferentially stimulates the synthesis of fibrinogen in human hepatoma cells. Whether the influence of EAA on the stress response may have some effect on the inflammatory response is unknown. The effects of stress on the inflammatory response are likely complex. Perhaps EAA decreases hypercoagulability by direct or indirect modulation of the inflammatory response (decreased production of IL-6) and subsequent inhibition of the "acute-phase response." Little is known about the influence of general anesthesia on the cytokine network, although ongoing studies at our institution have initially shown that the induction of general anesthesia has no significant immediate influence on levels of IL-6. The effect of postoperative epidural administration of local anesthetics and/or narcotics on IL-6 levels is unknown.

We support the approach taken by Tuman and colleagues of utilizing the thrombelastograph as a tool to measure fibrinogen-platelet interactions in the postoperative period, and believe that the most likely explanation for their results is an inhibition of the release of "stress-related" hormones, and subsequent inhibition of platelet adhesion-aggregation that is normally augmented by these stress hormones. Although not examined in the study of Tuman et al., another explanation may be inhibition of the "acute phase response" in the postoperative period, which if prolonged may predispose patients to development of a hypercoagulable state secondary to augmented fibrinogen synthesis. Further studies closely examining the influence of EAA on the inflammatory response may help further delineate the beneficial influence of postoperative epidural analgesia on morbidity/mortality in the surgical population.

In Response:

We thank Whitten et al. for their affirmative comments about our manuscript and compliment them for the additional insight they provide into potential mechanisms by which EAA influences coagulation. We agree with Whitten et al. that if EAA is indeed associated with lesser postoperative levels of circulating fibrinogen in patients with vascular disease, this may possibly be a result of inhibition of the "acute-phase response" with attenuation of augmented fibrinogen production, but is unlikely to be a result of changes in basal fibrinogen production. Whitten et al. correctly note that the observation of decreases in coagulability as early as 24 h after surgery in patients receiving EAA is inconsistent with the pharmacokinetics of basal fibrinogen production and metabolism. The most likely explanation for the altered fibrinogen-platelet effects measured on the first postoperative day is inhibition of the release of stress-related hormones such as catecholamines with subsequent reduction in the otherwise increased platelet activity produced by such mediators, as Whitten et al. contend. We further postulate that our findings could be related to decreases in plasminogen activator inhibitor with subsequent increases in fibrin(ogen) breakdown, but additional studies will be necessary to elucidate the exact mechanisms by which EAA influences coagulation.

Epidural Anesthesia and Analgesia in Vascular Surgery

To the Editor:

We read with interest the recent article by Tuman et al. and the accompanying editorial (1,2). There is convincing evidence that epidural anesthesia and analgesia (EAA) blunts the stress response to surgery (3); but, does this have a positive effect on outcome? Tuman et al. suggest that EAA modifies the coagulation system with salutary effects on adverse thrombotic events. In vascular surgery these adverse thrombotic events can involve either (a) the arterial graft, (b) the coronary arteries, or (c) the venous system. The resulting adverse outcomes are, respectively, (a) graft failure, (b) perioperative myocardial infarction (PMI), and (c) pulmonary embolism secondary to venous thrombosis.

Interpretation of the outcome portion of the Tuman study is difficult. The study population consisted of a heterogenous set of vascular procedures. Apparently, roughly half of the procedures involved infrainguinal reconstruction and the remainder were aortofemoral bypass procedures. It is plausible that EAA-induced changes in coagulation could have a salutary effect on graft failure in infrainguinal procedures. On the other hand, graft failure in aortofemoral bypass procedures is almost entirely due to technical difficulties where anesthetic technique is unlikely to have an impact. Therefore, it would be very helpful to know if the graft failures involved infrainguinal procedures. Tuman et al. note that all the patients who had graft failure had intraoperative arteriograms at the completion of the initial operation. Are completion arteriograms standard at the study institution or did the operating surgeons obtain them in these cases because technical difficulties were already suspected?

If indeed, graft failures in the control group all involved infrainguinal procedures, the relevant rate is 8/20 (40%) as half of the 40 control patients underwent infrainguinal procedures. This is much higher than the 5%–10% rate of early graft failure found in comparable series of infrainguinal procedures (4–6). Some retrospective data would be helpful here. What was the rate of early graft failure in the study institution before the initiation of the protocol? If the earlier rate of graft failure was more in line with that reported in other series (<10%), then we are left with the suspicion that, in this relatively small study, the luck of the draw placed a number of difficult, complication-prone procedures in the control group. Other outcome measures

---

The authors' opinions should not be construed as representing official views of the Departments of the Army or Defense.

were seriously confounded with the higher incidence of complications in the control group. Intensive care unit (ICU) stay was shorter in the EAA group; however, this appears to be almost entirely attributable to the need for reoperation for early graft failure among the control patients. A larger study may have found shorter ICU stays in EAA-treated patients, even after excluding patients who suffered complications.

It should be noted that there are many relevant variables that can affect the incidence of early graft failure after infrainguinal vascular procedures. Infrainguinal procedures encompass a number of different revascularization techniques: i.e., thromboendarterectomy, patch angioplasty, and bypass. For the bypass procedures, the type of conduit is an important variable: e.g., vein (reversed or in situ), polytetrafluoroethylene (PTFE, Gortex), or dacron. Finally, the site of distal anastomosis is important, e.g., suprapopliteal, infrapopliteal, or more distal. Assuring that this myriad of variables is comparable between control and treatment groups will be a daunting task for any future trial attempting to assess the effect of EAA on early graft failure.

One outcome measure in the Tuman study may not have been confounded with the higher incidence of graft failure in the control group, PMI. There were three PMI in the control group and none in the EAA group. Apparently these three cases did not involve any of the vascular complications. The *P* value for this difference was 0.07, which in a small study is at least suggestive that EAA could have a salutary effect on the incidence of PMI. Vascular surgery patients are at high risk for concomitant coronary artery disease, and PMI is a serious problem. Pathophysiologically, it seems plausible that the salutary effects on coagulation proposed by Tuman et al. could decrease the incidence of PMI in vascular patients. A recent, large prospective series comparing general and epidural anesthesia for infrainguinal arterial reconstruction found no difference in the incidence of PMI (7). However, in this study EAA was not continued into the postoperative period. As PMI often occurs in the first several postoperative days, rather than specifically during the operation, it appears that the stress response must be blunted well into the postoperative period to have a significant salutary effect on PMI. It is also not clear if postoperative epidural opioids would be sufficient or, as in this study, a combination of opioids and local anesthetics is required.

As mentioned in the editorial, outcome data must be forthcoming to justify the time and expense involved with EAA. We believe that Dr. Tuman and colleagues have provided a useful working hypothesis; but, unfortunately, this small study does not represent definitive outcome data.

In Response:

Baumgarten et al. provide insight into our work from a surgical viewpoint, and we are pleased to comment on their analysis of our study (1). Baumgarten et al. astutely note that most vascular graft failures after aortobifemoral bypass procedures are likely associated with technical difficulties. This does not, however, mean that hypercoagulability could not contribute to graft failure in these cases. Specifically, when technical difficulty is encountered during aortoiliac reconstruction, this is typically related to poor femoral anatomy in patients with severe aortoiliac atherosclerotic occlusive disease. Reduction of iliofemoral arterial lumen with less than optimal blood flow distal to the reconstruction can lead to inadequate limb perfusion, which probably can be compounded by a hypercoagulable state. Even though the frequency of this scenario is far less than seen with infrainguinal procedures, a salutory effect of epidural anesthesia and postoperative analgesia on coagulation as well as improvements in lower extremity blood flow secondary to central neuraxial sympatholysis could plausibly reduce graft failure in both types of procedures. This is consistent with our findings that there were two vascular graft failures in 20 suprainguinal procedures randomized to the GEN group, whereas none of the 15 suprainguinal procedures randomized to the GEN-EPI group were associated with graft failure. The distribution of complications according to type of revascularization and anesthesia group is shown in Table 1 and confirms that most of the graft failures involved infrainguinal procedures.

Table 1. The Distribution of Complications According to Type of Revascularization and Anesthesia Group

	All cases		Infrainguinal revascularization		Aortoiliac reconstruction	
	GEN	EPI	GEN	EPI	GEN	EPI
No. of cases	40	40	20	25	20	15
No. vascular graft failure	8	1	6	1	2	0
No. deep venous thrombosis	1	0	1	0	0	0
No. myocardial infarctions	3	0	1	0	2	0
No. thrombotic complications[a]	11	1	7	1	4	0

GEN, general anesthesia; EPI, epidural anesthesia.
[a] Number of patients with thrombosis of vascular graft, coronary artery, or deep leg vein, not number of individual occurrences; one patient had both myocardial infarction and vascular graft failure.

Even though the subpopulation undergoing infrainguinal revascularization was smaller than the overall study population, statistical significance was still achieved when comparing the incidence of vascular graft failure in the GEN-EPI group (1/25) with that in the GEN group (6/20; $P = 0.017$). Completion arteriograms are standardly performed at our institution for all patients undergoing infrainguinal revascularization, and as noted in our paper, none of the patients with vascular graft failures had evidence of technical problems such as intimal flap or anastomotic problems and all had evidence of adequate outflow on completion of operation. The two patients who experienced lower extremity ischemia after aortoiliac reconstruction both had postoperative arteriograms that demonstrated no technical problems related to the graft or anastomotic sites, but did reveal residual atherosclerotic involvement infrainguinally that was not thought to be significant during the preoperative surgical evaluation. Both of the latter patients were markedly hypercoagulable postoperatively, and we believe that this hypercoagulability contributed significantly to their adverse vascular outcome. We would, however, agree with the implication of Baumgarten et al. that in the absence of abnormalities of vessel architecture (such as endothelial damage or luminal compromise with subsequent aberrations in blood flow patterns and velocity) hypercoagulability is probably much less important to surgical outcome than when such abnormalities are present. Indeed, this is likely to be the very reason that we observed such profound effects on graft failure rate in the infrainguinal group. This subset of patients represents a population at variable but consistently high risk of vascular complications. Simple comparison of overall vascular complication rates is dangerous without careful analysis of population demographics, precise quantitation of vascular anatomy, and evaluation of other subtle but important factors such as perioperative coagulation management (aspirin, low dose heparin or dextran). The overall incidence of vascular complications after infrainguinal revascularization in our study was 15.5% (7/45), and is a reflection of the severity of vascular disease in the study patients. This is consistent with other recently reported data (2) that confirm our findings that epidural anesthesia with postoperative analgesia has a beneficial effect on vascular complications after lower extremity revascularization. The Johns Hopkins experience revealed that regrafting or thrombectomy was more common in 51 patients randomized to general anesthesia than in 49 patients randomized to epidural anesthesia/analgesia (22% vs. 4%, $P < 0.01$) (2), and these results are remarkably similar to those at our institution. The overall rate of graft failure in our study did not differ markedly from that previously observed at our institution and reflects the large number of difficult and complication-prone patients treated for lower extremity revascularization. The similarity of results from two institutions studying the same phenomena strongly suggests that Baumgarten et al. need not be left with the "suspicion that . . . the luck of the draw placed a number of difficult, complication-prone procedures in the control group."

Baumgarten et al. correctly point out that a large number of surgical variables could plausibly affect the incidence of early graft failure after infrainguinal revascularization. Grafting to distal vessels was equally frequent in both randomized anesthesia groups. Most studies suggest that patency rates after lower extremity revascularization are better when saphenous vein is used as the conduit compared to when synthetic materials such as Gortex or dacron are used because of lack of usable vein. In our study, a lower frequency of vein graft use (3/25) in the EPI group compared to the GEN group (7/20) actually represents a reverse bias against the occurrence of better graft patency in the EPI group. During the planning of our study we recognized that the use of synthetic versus saphenous vein graft was a potentially important factor influencing surgical outcome. However, the decision to use Gortex rather than the preferable vein graft can often be made only after intraoperative evaluation of potential native conduits, so that preoperative randomization of anesthesia type matched to a single type of conduit would be impractical and require another study design such as placement of epidural catheters in *all* patients with subsequent intraoperative randomization to an epidural treatment group. Indeed, post hoc evaluation of the 35 infrainguinal procedures that required use of Gortex only confirms the overall findings of our study. In this subset, the incidence of acute vascular graft failure was also very much less in the EPI compared to the GEN group (4.5% vs. 30.8%, $P = 0.033$). For the reasons discussed above, we are confident that more complicated and elaborate study designs that attempt to more closely control for potentially confounding anatomic variables will validate our findings.

We agree with Baumgarten et al. that prolongation of ICU stay has a multifactorial etiology, but refute the contention that prolonged ICU stay "appears to be almost entirely attributable to the need for reoperation for early graft failure." The average duration of ICU stay among the 9 patients in our study with graft complications (2.77 ± 3.6 days) was not significantly different from the 71 patients without graft complications (2.37 ± 5.2 days, $P = 0.82$). A logistic regression model used to predict prolonged ICU stay (>3 days) based on the postoperative complications listed in Table 4 of our paper indicates that cardiovascular and major infectious as well as overall complication rates were the only significant multivariate predictors of prolonged ICU stay. Graft failure, including necessity for reoperation or amputation, had neither a multivariate nor univariate association with prolongation of ICU stay. Not surprisingly, prolongation of ICU stay had the greatest correlation with total number of serious complications, and this in turn had a strong association with type of anesthesia and analgesia.

Finally, we strongly agree with Baumgarten et al. that our findings suggestive of an apparent beneficial effect of anesthetic management on the occurrence of PMI in the EPI group are very likely attributable to the postoperative use of epidural analgesia. A common denominator of prospective studies that have demonstrated beneficial effects of central neuraxial techniques on this outcome is the use of continuous postoperative epidural analgesia. Failure to consistently continue epidural use into the postoperative period is a common feature of all studies that do not demonstrate such salutory effects. Many of the questions raised by Baumgarten et al. are important, and we agree that further critical investigation will be necessary to refine our understanding of the effects of EAA that we have reported in our study.

Differential Awakening

To the Editor:

I would like to propose a new phenomenologic term, "differential awakening," for the clinical anesthesiologist. Over the years as a practicing neuroanesthesiologist, I and others have observed that patients with cerebral ischemia or mass lesions frequently show evolving lateralizing neurologic signs on awakening. Immediately on awakening, unilateral return of motor function is frequently delayed but improves, and returns to complete function over about 10–30 min, thus, the term "differential awakening."

This process is clinically significant because it is clearly different from a surgical neurologic deficit that is expected to return slowly. It is also different from immediate surgical complications that might require reopening of the cranium or a computed axial tomographic scan for further diagnosis. Three theories could explain the phenomenon of differential awakening. First, anesthetics enter the brain and are trapped in areas that are injured by ischemia or trauma, and at the end of anesthesia, these anesthetics escape more slowly from the injured areas. Second, perhaps the areas of cerebral injury are more sensitive to low concentrations of the anesthetic, resulting in a slower unilateral emergence. Last, in patients who suffer destructive neurologic damage with full recovery, it is believed that secondary pathways compensate and accomplish the function of the destroyed neurons; perhaps these secondary pathways are only functional in a completely awake state.

Complete Tolerance to Opioids

To the Editor:

Complete tolerance is a well-known, but rarely seen, complication of prolonged opioid administration. Aggressive pain management in cancer patients, who are living longer, is now presenting us with this clinical problem. Cross-tolerance to other drugs makes analgesia even more difficult.

Recently, we treated a 49-yr-old man with intractable pain from a pelvic chondrosarcoma who demonstrated this problem. This patient had received maximal chemotherapy and, for more than a year, had used morphine at home through an intravenous pump. In the hospital, we failed to achieve analgesia or sedation with morphine infused at 1200 mg/h or with hydromorphone at 800 mg/h. A midazolam infusion at 10 mg/h produced little effect. Finally, an intravenous infusion of ketamine, titrated to $2.7\ \mathrm{mg \cdot kg^{-1} \cdot h^{-1}}$, produced satisfactory pain relief while the patient remained awake. Unfortunately, we could not further refine this therapy because the patient died 30 h after starting ketamine.

Current research on opioid receptors reveals three primary types—mu, kappa, and delta—and several subtypes of these. Ketamine acts at multiple thalamic and spinal cord sites, including opioid receptors (1). Ketamine also inhibits the dorsal horn nociceptive receptor stimulated by *N*-methyl-D-aspartic acid (NMDA) (2,3). That ketamine produced conscious analgesia in our opioid-tolerant patient may indicate it inhibited nociceptive pathways through NMDA receptor antagonism. The larger-than-normal ketamine requirement may indicate partial cross-tolerance with morphine, which occurs in animals (4).

Perhaps ketamine or other NMDA antagonists will prove useful as adjuvant drugs in cancer patients receiving high doses of opioids. We would like to see more research or clinical reports in this area.

Is the "Kneeling" Prone Position as Dangerous as the Sitting Position for the Development of Venous Air Embolism?

To the Editor:

We are extremely impressed with the excellent report by Albin et al. (1) concerning major venous air embolism (VAE) occurring in three patients who were undergoing spinal surgery in the prone "kneeling" position. It would also have been interesting to know the time period over which these three complications occurred.

We inserted pulmonary artery catheters in some of our patients who were scheduled for lumbar laminectomy with fusion and were positioned in the Andrew's frame. These patients had normal myocardial function, and we observed pulmonary capillary wedge pressures (PCWP) ranging from 5 to 7 mm Hg after induction of anesthesia and before positioning in the frame. As soon as the patients were placed in the kneeling position, PCWP decreased to approximately zero accompanied by a similar decrease in central venous pressure (CVP). We elevated the patients' legs while they were still prone before surgery started, with a resulting increase of PCWP and CVP. During these procedures, crystalloids and colloids were given in an attempt to increase CVP. When returning the patient to the supine position at the end of surgery, a marked increase in PCWP and CVP was also noted and required the intravenous administration of furosemide to avoid the development of pulmonary edema.

Based on these observations and the work of DiStephano et al. (2), we presume that the decrease in PCWP is a result of blood pooling in the legs when they are positioned lower than the heart despite the precaution of wrapping the legs in antiembolism elastic stockings (TED hose) with sequential pneumatic compression. We suspect that the kneeling position markedly increases the pressure gradient between the surgical site and the right side of the heart by producing relative central hypovolemia even before surgery is started. This is then aggravated by surgical blood loss, especially with the delay of retransfusion of blood volume imposed by the cell saver that is routinely used in these cases. The relatively low CVP combined with the length of these procedures (8–12 h of surgical time at our institution) obviously predispose to increase the risk of VAE.

We consider that this subject is of the utmost importance and, in our opinion, these procedures should be carried out with the same level of attention that is applied to anesthesia for surgery in the sitting position. Clearly efforts should be made to reestablish a reasonable level of CVP. We agree with Dr. Albin that any occurrence of VAE should be reported in the medical literature so that we can ascertain the true incidence of this complication under these conditions.

A Special Surgical Technique Leads to Venous Air Embolism During Neurosurgery of the Spine

To the Editor:

Dr. Albin et al. (1) have pointed out the need of reporting cases of venous air embolism (VAE) to estimate its frequency. We would like to report three cases of VAE during neurosurgery of the spine involving the use of homologous spongious bone graft.

The graft was prepared by breaking down bone into small fragments and collecting these fragments in a funnel. This material was then injected into the intervertebral compartment by applying pulsatile pressure with a piston. This technique was used in three patients and led to VAE every time.

The demographic variables are summarized in Table 1. In each case, after graft injection (funnel and piston), a typical millwheel murmur was heard in the esophageal stethoscope with a concomitant decrease in the end-tidal CO_2. The prophylactic placement of a vent catheter in the discal compartment was ineffective in preventing VAE in case 3.

Venous air embolism has been described during lumbar laminectomy (1). The type of positioning of the patient (2), the vena cava pressure (3), and the gravitational gradient right heart-operative field are important factors. So far, the placement of homologous bone has not been associated with VAE. Although no precordial Doppler was installed, the diagnosis of VAE with the aid of the esophageal stethoscope was suspected in each case.

The causative mechanism in our three cases of VAE is thought to have been a "bicycle-pump" phenomenon during graft placement: the pulsatile movement through the funnel creates a high pressure in the discal compartment,

Table 1. Patient Demographics

	Cases		
	1	2	3
Age (yr)	59	51	33
Sex	M	F	M
ASA physical status	III	II	II
Surgery	Laminectomy and fusion L3-S1	Discectomy L5-S1	Discectomy L5-S1
Position	Prone	Prone	Prone
Millwheel murmur (ES)	++	++	++
ET_{CO_2} decrease (mm Hg)	6	10	7
Associated events	Tachycardia, elevated ST-segment	Wheezing	None
Sequelae	None	None	None

ET_{CO_2}; end-tidal CO_2; ES; esophageal stethoscope.

which produces VAE; air enters the venous system either via a peridural vein or via the venous channel of the bone.

In conclusion, injection of spongious graft using a funnel and piston creates high pressure in the discal compartment and leads to VAE. This technique clearly has the potential to enhance the chances of a VAE.

Resistance to Curare, Upper Motor Neuron Dysfunction, and Antiepileptic Treatment

To the Editor:

We wish to make some comments on the article by Moorthy et al. concerning the resistance to nondepolarizing muscle relaxants (NDMRs) in patients with cerebral palsy and in patients treated with antiepileptic drugs (1).

From a neurophysiologic point of view, curarization (2) and myasthenia gravis (MG) (3) are both assessed by the same diagnostic technique. We think, therefore, that observations made in myasthenic patients could be useful in understanding whether the resistance to vecuronium reported by the authors should be ascribed to pharmacodynamic or pharmacokinetic factors.

In hemiparetic patients who subsequently acquire MG and in myasthenic patients who subsequently acquire hemiparesis, electromyographic evidence of MG is restricted to muscles contralateral to the side of the motor deficit (4,5). In other words, decentralized muscles of patients with upper motor neuron dysfunction may become resistant to antibodies occurring in MG just as they become resistant to NDMRs.

Nondepolarizing muscle relaxants and anti-acetylcholine-receptor (AChR)-antibodies have different mechanisms of action. Junctional AChRs, however, are the common target upon which the action of both is exerted and effects are quantified.

We think, therefore, that the appearance of a new population of junctional AChRs should be regarded as a possible consequence of upper motor neuron dysfunction and as a possible explanation of the resistance to NDMRs exhibited by decentralized muscles.

There are no reports indicating that signs and symptoms of MG can be relieved by the use of antiepileptic drugs. On the contrary, our clinical impression is that the treatment of MG is more difficult when MG is complicated by epilepsia. In other words, antiepileptic treatment may be followed by resistance to the action of NDMRs, but not to the action of anti-AChR-antibodies.

We retrospectively examined the intensity of neuromuscular blockade produced by the tracheally intubating dose of NDMRs (pancuronium or vecuronium) in 72 neurosurgical patients. Decentralization was present in 34 examinations. Motor deficit was not present in the remaining 38. The mean value of T-1 was 37.5% in the paretic patients and 12.8% in the nonparetic patients ($P < 0.001$, one-way analysis of variance). The mean value of T-4 was 22.6% in the paretic patients and 2.2% in the nonparetic patients ($P < 0.001$, one-way analysis of variance).

Chronic antiepileptic treatment was present in 20 patients. No significant correlation was found between antiepileptic treatment and intensity of the neuromuscular blockade. The mean values of T-1 and T-4 were 24.0% and 11.6% in the treated paretic and nonparetic patients, respectively, and 24.5% and 11.9% in the untreated paretic and nonparetic patients. The difference in T-1 and T-4 values between paretic and nonparetic patients was still significant ($P < 0.001$, one-way analysis of variance) when adequate correction for the antiepileptic treatment was performed.

Even though the number of patients is small in our series, we think that our data and observations made in myasthenic patients support the hypothesis that pharmacodynamic factors should be considered in patients with upper motor neuron dysfunction, whereas pharmacokinetic factors should be considered in patients treated with antiepileptic drugs.

Scientific Approach to Presenting and Summarizing Data

To the Editor:

Descriptive statistics and inferential statistics are the main tools for scientific communication in biomedical journals. Descriptive statistics include expressions of means, standard deviations (SDs), coefficient of variation (CV), proportions, medians, ranges, and percentiles. Inferential statistics include standard errors (SEs), confidence intervals (CIs), and various tests that yield *P* values for differences in means, proportions, and other descriptive data (1). In this communication I would like to suggest some methods to improve the quality of presenting and summarizing data in our journals.

I examined the articles published in *Anesthesia & Analgesia* in the year 1991 to determine how data are presented and summarized. There were 208 articles related to laboratory and clinical investigations. In 90 (43.27%) of these articles, the data were summarized as mean ± SD and in 91 (43.75%) as mean ± SEM. The data in the rest of the articles were summarized as medians, ranges, percentages, etc. The suggestion that all journals discontinue the use of the ± sign was made in 1986 by Altman and Gardner in a letter to the *The Lancet* (2). But this sign continues to appear in the *Anesthesia & Analgesia* journal regularly. It was also stated in the same letter that SEM should not be used to indicate the variability of a set of observations. As mentioned above, in 43.75% of the articles published in 1991, authors used SEM to indicate the variability. Variability is best indicated by SD or CV (SD/mean %) according to the situation (3,4). The CV is most useful as a descriptive tool in situations in which a change in the conditions under which measurements are made alters the SD in the same proportion as it alters the mean (3). Glantz suggested that SD, not SE, should be used to summarize the data (5). The fact that SE is inappropriate for indicating the variability of a sample must be clearly understood. By itself, SE provides limited information. It is used to estimate the CI, which is very informative (6,7). The CI is a range of values that is likely to cover the true, but unknown, population value. Thus SE is an inferential statistic, not a descriptive statistic (8). Confidence intervals can be computed from SEs for every sample statistic (means and their differences, proportions and their differences, correlation coefficients and regression coefficients, etc.) using the standard formulas (3,6,7).

There are several advantages of presenting the data (in tables and figures) as CIs wherever appropriate. Confidence intervals provide more information than hypothesis testing by the use of *P* values (6). Differences of no real interest can be statistically significant with large samples, whereas clinically important effects may not be significant when the sample size is small. Confidence intervals provide useful information in studies with large as well as small samples (9) and help us to avoid some misinterpretations that result from dichotomous conclusions from the significance tests based on *P* values (10,11). In addition, CIs also have a link to the outcome of hypothesis tests. For example, when the result of difference between two means is significant at the 5% level, the 95% CI for difference in their means will not encompass zero (7). Difference in proportions summarized in 2 × 2 tables are usually tested by Fisher's exact test or χ^2 analysis with Yates' correction. But 95% CI for difference in proportions gives more information than hypothesis testing by either of the above two methods. In addition, meaningful interpretations of results of different studies can be derived when the difference in proportions are given in 95% CIs rather than when the results are interpreted by significant testing based on *P* values (12). Finally, according to Snedecor "the purpose of an experiment is to produce a sample of observations which will furnish estimates of parameters of the population together with measures of uncertainty of these estimates" (13). Confidence intervals satisfy the requirements for a meaningful inference from an experiment because they indicate the degree of imprecision of the sample as an estimate of the population value.

In summary, variability in a sample may be presented as SD without the use of the ± sign, or as CV according to the situation. Confidence intervals, if appropriate to the type of study, should be used for major findings in both the main text of the paper and its abstract (6). In the present day and age of rapidly growing medical literature in a plethora of journals, we generally rely on computer-assisted literature search programs to access different publications. As these services allow us to get only the abstracts, the suggestion that the more informative CIs be presented in the abstracts appears very attractive. This letter is essentially an echo of what statistical experts have been expressing during the past few years. The suggestions if followed will further improve the quality of scientific communication in *Anesthesia & Analgesia* and in other journals of our speciality.

Esterase Nomenclature: A Confusing Topic

To the Editor:

The classification of cholinesterases is so unclear that even leading anesthesiology textbooks carry errors in their description. Page 473 of *Clinical Anesthesia* edited by Barash, Cullen, and Stoelting states that "pseudocholinesterase degrades acetylcholine released at the neuromuscular junction" (1). Instead, it should read "acetylcholinesterase" or any of the other multiple terms used to designate this enzyme.

This letter is not to point out a typographical mistake but to illustrate that esterase nomenclature is very confusing. True cholinesterase (E.C.3.1.1.7) is also known as choline esterase I or specific, cholinesterase, acetylcholine hydrolase, acetylcholinesterase, or erythrocyte cholinesterase. Whereas pseudocholinesterase (E.C.1.1.8) is also known as choline esterase II or unspecific, butyrylcholinesterase, benzoylcholinesterase, acylcholine acyl-hydrolase, serum cholinesterase, or plasma cholinesterase (2,3).

A Simple Replacement for the Pulmonary Artery Catheter Balloon Syringe

To the Editor:

During the use of a pulmonary artery catheter, the 3.0-mL balloon inflation syringe may be misplaced. This may necessitate replacement with a regular 3.0-mL syringe and the expense of opening a new kit to obtain the special syringe. Manufacturers recommend that no more than 1.5 mL of air be used to inflate the pulmonary artery catheter balloon. If too much air is injected, it can cause balloon or pulmonary artery rupture. We describe a simple and easily accessible method to prevent excessive air injection.

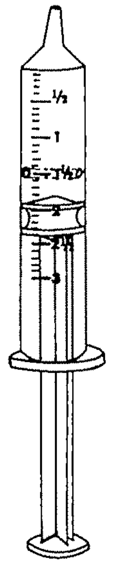

Figure 1. Pulsator blood gas syringe with the 16-gauge needle at the 1.5-mL mark.

Using a 3-mL pulsator blood gas syringe, the plunger is withdrawn and a 16-gauge needle is used to pierce two holes through the cylinder of the syringe at the 1.5-mL mark (Figure 1). The 16-gauge needle is then removed. These holes will permit balloon inflation with 1.5 mL of air, but will prevent overinflation as there will be an air leak above the 1.5-mL mark. Because this is a closed system, sepsis is not a concern. Like the original syringe, this one will also allow passive deflation rather than active deflation, which may cause balloon rupture.

Book Reviews

Final Approach

John J. Nance. New York: Ballantine, 1990, 407 pp, $4.99.

I often wait for airplanes and I like to read "airport novels." I have never submitted book reviews on them before.

A Boeing 737 is waiting "short of the runway," i.e., next for takeoff, awaiting the landing of an Airbus 320 jumbo jet, which smashes into the 737 broadside. Severe thunderstorms and lightning had prompted the waiting pilot to advise, minutes earlier, to both the tower and the incoming Airbus, that there might be dreaded windshear and that perhaps the Airbus (both were from the same company) ought not to attempt landing. The 737 pilot is rewarded with radioed pilot jargon meaning "butt out" from the Airbus pilot. Recently, the *Wall Street Journal* published an article about several senior corporate (nonairline) executives who were fired for intimidation and for creating an atmosphere in the workplace that was nonconducive to the making of valid contributions by professionals who are subordinates.

Final Approach was written by John Nance, a former airline captain and aviation safety expert. It is, on one level, a skillfully crafted "thriller" novel (yes with a love interest for the protagonist, with more than token feminism). On this level, it is about the investigation of the crash by the National Transportation Safety Board (NTSB), which is charged with determining the cause and making recommendations to the FAA vis à vis possible changes in safety procedures or inspections.

On a different level, this novel opened my eyes to an innovative way of thinking about fear/intimidation/dogma/domination in the workplace by someone designated (either by fate, custom, or self) to be CAPTAIN. Nance elegantly crafts the point that the copilot is *also a professional*. Safety-related advice, suggestions, and information from that individual can only add to the total margin of safety. The "captain" must create the kind of atmosphere wherein all professionals who work in the same workplace are encouraged to think, innovate, be watchful, and contribute. To be sure, the captain is still the final decision maker, but must ask for input, acknowledge it, accept it when it makes sense to do so, and *give credit* to team members who contribute. It is even more difficult to create an atmosphere in which a "copilot" will be empowered to "take control" when it becomes obvious, in the copilot's best professional judgment, that the captain is impaired and unable to perform with competence. According to Nance, this is incredibly difficult to get across to airline captains. Airlines publicly tread lightly on the issue, but they *are* tackling it. They call it "cockpit resource management." Turns out that such an atmosphere of intimidation and fear had been created by the captain of the Airbus that . . . well I won't tell you the rest. Suffice it to say that action by the copilot 0.7 seconds sooner would have . . . there I go—I said I wouldn't tell you any more about the novel!

Everyone who works in operating rooms (the British still insist on calling them "theatres"), where surgery (according to the media) is "performed," understands what I'm talking about here. The novel aspect of Nance's point of view is the idea that if a professional is intimidated, or shuts down to a level where he/she merely follows orders, then that professional has *voluntarily abdicated his/her critical mandate to maximize all possible margins of patient safety*.

Do we discipline people for abusive, intimidative, fear-engendering behavior in operating rooms? Seldom. There are documented extreme cases, some involving actual physical violence and real endangerment, which were not followed by remotely valid discipline to the perpetrators. I have fought against this for many years, long before I read Nance's *Final Approach*, but I did so mostly out of a well-formed sense of fair play. W. Edwards Deming, the American who is revered as a demigod in Japanese industry, taught as one of his now-famous 14 points: "drive out fear." *Final Approach* is not about anesthesia and is not written by an anesthesiologist, but it *is* about one of our most pervasive, perfidious, insidious, even deadly problems. It is time we began to understand the real effects of intimidation and domination of professionals on patient safety in the operating room. Perhaps *Final Approach* will stimulate thinking. Thinking about it and talking among ourselves isn't enough. Again to use another of Deming's points, we need to "take action."

Anesthesiology Review

R. J. Faust, R. F. Cucchiara, L. N. Milde, S. H. Rose, and T. N. Spackman, eds. New York: Churchill-Livingstone, 1991, 535 pp, $37.95.

As residents approach the end of the academic year, they seek a convenient review method for the American Board of Anesthesiologists' (ABA's) written examination. *Anesthesiology Review*, edited by Ronald J. Faust and colleagues of the Mayo Medical School's Department of Anesthesiology, is a new review book that is designed as a study aid for the ABA's examination. Its aim is to "fill the gap" between the ABA's "content outline" for the written examination and the standard textbooks in the field. *Anesthesiology Review* addresses examination preparation by concentrating on topics listed in the "content outline" and the "key words list." The "key words list" is a list of topics answered incorrectly on the in-service examination that is sent to

©1992 by the International Anesthesia Research Society

residency program directors and examinees after the examination has been graded. Thus, *Anesthesiology Review* is essentially a "key words" answer book with each chapter covering a topic from the "key word list" provided by the ABA.

The book's organization closely follows the ABA's "content outline." It is divided into three parts: Physiological Sciences, Physical Sciences, and Clinical Sciences. Each part is further divided into sections that are composed of brief, one- to three-page chapters. Each chapter highlights a specific topic that originates from the "key word list." The chapters emphasize the most important points of each topic. They often contain helpful figures, tables, and outlines. In addition, most chapters cite references and contain a short list of suggested readings from major anesthesiology texts.

If the reader is not reviewing topics for the examination, the organization is unsettling because many related topics are spread over several sections of the book and some topics are divided into several separate chapters. For example, with respect to the topic of the hepatobiliary system, the section Physiology contains two chapters that deal with the liver: "Mechanisms of Hepatic Drug Metabolism and Excretion" and "Hepatic Physiology and Preoperative Evaluation." The second section contains two additional chapters that deal with this system: "Hepatic Effects of the Inhalation Agents" and "Narcotic Induced Right-Upper Quadrant Pain," and a subsequent section contains chapters covering anesthesia for patients with hepatocellular disease and acute and chronic alcoholism and anesthesia. While reading about a given topic, I often found myself thinking about issues and problems that were addressed in an entirely different section of the book.

Despite this confusing method of organization, many of the individual chapters follow a format that serves to speed review, aid in comprehension, and enhance memorization and recall of the material. Most chapters have a hybrid mixed format that consists of brief introductory paragraphs followed by either an outline or by paragraphs in which important words or phrases are highlighted. In addition, figures, tables, and diagrams are used where appropriate. This format is effective in providing a succinct review of the essential material. A majority of the chapters follow this mixed format, but some of the chapters are all prose. The prose format is easier to read, but less suited for review and study. Other chapters consist of a group of tables, outlines, and figures that are connected by a few sentences of text. I found those chapters to be unappealing because they are too skeletonized and difficult to read. The editors' failure to enforce a consistent format has resulted in a collection of chapters that vary in format, layout, and quality of presentation. It is unfortunate that the mixed format was not adopted as a standard chapter format because it is so effective and well suited to a review book.

Most of the chapters were written by residents and fellows in training at the Mayo Medical School's Department of Anesthesiology. Some of their chapters were superb, demonstrating a fresh approach to the material, but others lacked inspiration. The remaining chapters were written by well-established authors from the anesthesiology literature. In general, their chapters provided a more consistent presentation. Also, many of the strengths of Mayo's department are reflected in the content of the book. For example, most of the sections that cover neurologic or pulmonary considerations in anesthesia are excellent.

There are two appendices at the end of the book. One is a reprint of the ABA and ASA *Content Outline for In-Training Examinations*. This is a useful study aid because it helps focus the student's attention on the most important issues and topics. It is quite convenient to have this attached to the review book. There is also a "user-friendly" index at the back of the book that indicates topics and makes special notation of tables and figures.

In summary, *Anesthesiology Review* is a useful review of selected topics and a helpful and efficient study aid for the ABA's written examination. It does not (nor do the editors intend it) to replace the existing and established anesthesiology texts. It is an excellent comprehensive review book for the ABA's written examination, and I recommend it to my colleagues who are studying for "the boards" this spring.

William G. Filmyer, MD
Columbia-Presbyterian Medical Center
New York, New York

Atlas of Regional Anesthesia

David L. Brown. Philadelphia: W.B. Saunders, 1992, 320 pp, $95.00.

This is certainly a beautifully illustrated book covering a wide number of regional anesthetic techniques that would be useful for both acute and chronic situations. The book is unusual in that there are a number of cross-sectional anatomic illustrations that enable a three-dimensional concept of the anatomy to be visualized and hence the approach to be easily understood. A variety of techniques are offered for most blocks, and at the end of every chapter is found a useful section—"pearls" (personal tips and advice from the author).

Considering David Brown's experience, it might have been helpful to have extended chapter 1 to cover the pros and cons of available equipment. Other regrets were the absence of newer techniques such as cross-section echocardiography and indwelling catheters. Diagrams failed to illustrate the best position of the anesthetist's hands and where to stand (although this was explained in words). The anatomy descriptions were well written, but one often had to turn the page to find the relevant illustration, which detracted from the visual image.

This is probably not an essential personal book but well worth having for those interested in expanding their regional techniques. They will find it easy to use.

Myofascial Pain and Dysfunction, The Trigger Point Manual, Volume 2: The Lower Extremities

J. G. Travell and D. G. Simons. Baltimore: Williams & Wilkins, 1992, 607 pp, $93.00.

Pain that is persistent beyond the 2–6-week period of injury and inflammatory responses associated with tissue trauma or systemic illness coincides with hypersensitivity either at the neurovascular junction (sympathetically maintained pain) or at the myoneural junction (myofascial pain syndrome). In the realm of multidisciplinary pain management, anesthesiologists frequently serve as diagnosticians, using their expertise to advise patients regarding further physical and psychological rehabilitative therapy. Injections of local anesthetic are often used to identify the somatic correlates of a chronic pain syndrome. A systematic approach to individual diagnosis is based first on history and physical examination. Sympathetically maintained pain (such as reflex sympathetic dystrophy) begins distally in an inflamed, immobile extremity, and is attributed to altered norepinephrine sensitivity at the neurovascular junction. Pain that spreads from the trunk outward (such as low back pain, with or without leg pain) is more likely associated with localized acetylcholine hypersensitivity at the myoneural junction. Low back pain may be the most common complaint of patients referred to an anesthesiologist for diagnosis and recommendations regarding further pain management. Usually pain in these patients is associated with palpable "trigger points" within weight-bearing muscles on the painful side. Presently, there is no systemic medication that results in localized desensitization to acetylcholine at the myoneural junction; but repeated needling of the most sensitive points can produce muscle bundle relaxation. When needling techniques are combined with proper and repeated stretching exercises, ultimate resolution of chronic pain and muscle dysfunction can occur.

The second volume of *Myofascial Pain and Dysfunction, The Trigger Point Manual* specifically addresses posttraumatic myofascial pain syndromes that originate in the low back and that may also involve the lower extremities. After an introductory Pain Guide, which is designed to allow the practitioner to skim quickly muscle groups for trigger points, chapters are sequentially arranged by myotomal segment, beginning at T-12 with the quadratus lumborum. Organization of material within each chapter is clear and consistent, beginning with a description of the pain complaint, patient examination, and trigger point identification. Techniques for injection and specific stretching exercises are included for each involved muscle. Once trigger points are identified and inactivated, a search for the inciting causes of the pain and dysfunction can begin. Reactivators of localized myoneural hypersensitivity can include biochemical disturbances, emotional stressors, chronic posture adaptations (particularly in the workplace), musculoskeletal imbalance, and chronic nerve root swelling or dysfunction. Unless individual reactivators are addressed and resolved, pain-related disability will continue. Accordingly, each chapter contains specific descriptions of posture, activities, and exercise that may reactivate individual trigger points, as well as suggestions for therapeutic approaches to patient management. Although anesthesiologists are unlikely to become involved in all phases of rehabilitation, an understanding of the process is mandatory when reviewing each patient's progress.

As a guide to the diagnosis and management of posttraumatic pain syndromes, *Myofascial Pain and Dysfunction, The Trigger Point Manual, Volume 2: The Lower Extremities* is a book no anesthesiologist involved in the diagnosis and management of patients with chronic back (and leg) pain can afford to be without. Volume 2 was published in 1992, and can be purchased in a two-volume set with the 1983 Volume 1, which describes myofascial pain syndromes of the neck, chest, and abdomen.

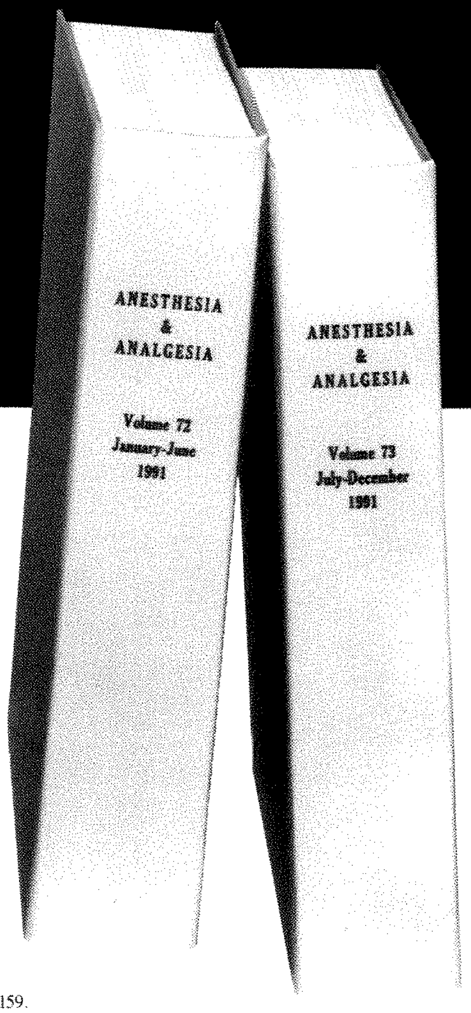
An invitation for current subscribers!

Bound volumes of

ANESTHESIA & ANALGESIA



Reserve your 1991 bound volumes now! As a special service to current subscribers only, **ANESTHESIA & ANALGESIA** is available in bound volumes, priced at $80.00 (US) and $100.00 (international). The two bound volumes for 1991 (volumes 72 and 73), are bound in buff buckram – the same high quality binding you would find in a library – with stamped lettering on the spine. These handsomely bound volumes include:

- complete author and subject indexes
- editorial content only, with all advertising removed
- sturdy bindings for durable reference

From now on, when you receive your regular monthly copy of **ANESTHESIA & ANALGESIA,** don't hesitate to tear out or mark up articles of particular interest – because your specially bound volumes will include every issue in perfect condition, to help you keep your personal library complete, organized, and current.

Reserve your 1991 bound volumes by returning the order form below.

Clip and mail to **Elsevier Science Publishing Co., Inc.**, P.O. Box 882, Madison Square Station, New York, NY 10159.

ORDER FORM

☐ Please send me bound volumes 72 and 73 for **ANESTHESIA & ANALGESIA.*** Both volumes will be shipped together in 1992 for a total cost of $80.00.

Outside the U.S., please add $20.00 for postage and handling.

☐ Please start my annual standing order to receive bound volumes of **ANESTHESIA & ANALGESIA.** Two bound volumes will be shipped together automatically at the end of each year.

*Offer available only for subscribers to **ANESTHESIA & ANALGESIA.** Please allow 4-6 weeks for receipt of your bound volumes.

Please return to:
Elsevier Science Publishing Co., Inc.
P.O. Box 882
Madison Square Station

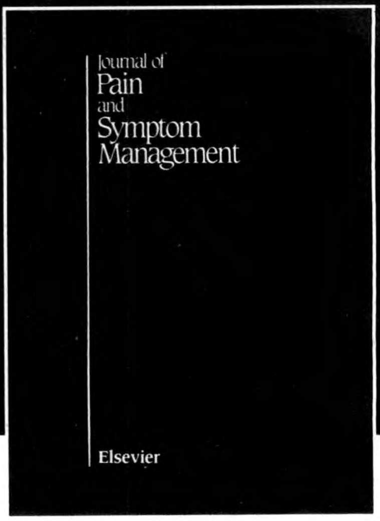
Covering the Full Spectrum of Pain and Symptom Management

Journal of Pain and Symptom Management



Journal of
Pain
and
Symptom
Management

Elsevier

Editor: **Russell K. Portenoy, MD,**
New York, New York
Founding Editor: **George Heidrich, RN**

Journal of Pain and Symptom Management provides the professional with the results of important new research on pain and its clinical management.

This peer-reviewed, internationally respected journal offers a much-needed forum for the exchange of ideas and information among clinicians and researchers working in pain and symptom management, including oncologists, anesthesiologists, neurologists, pharmacologists, nurses, therapists, psychologists, and psychiatrists.

Written By and For Professionals in Pain Management

Journal of Pain and Symptom Management boasts an international editorial board comprising leading researchers and clinicians. Each board member is an active figure in the field of pain research and management and a major contributor to literature on the diagnosis, treatment, and control of pain.

Broad in Scope

Articles focus on the full spectrum of patient care: how to treat the patient presenting with pain; how the family of the patient can cope and assist; how the medical team can best work as a unit. Reports discuss methods for symptom identification and pain management and examine pharmacologic as well as psychologic methods of treatment. Case results are reported and tables and graphs supplement many of the findings.

Applicable to Practice

Journal of Pain and Symptom Management is devoted to providing information that is of direct application to your practice. Along with Original Articles, Review Articles, and Clinical Reports; Special Articles supplement each issue. Sections not found in other journals include an "Information Exchange" providing updates and results from important meetings, symposia, sessions, and seminars.

Keep pace with the changes taking place in your field. Become a subscriber to **Journal of Pain and Symptom Management!**

Abstracted and Indexed in: Excerpta Medica; Psychological Abstracts; MEDLINE; Child Development Abstracts and Bibliography; Nursing Abstracts; International Nursing Index; Current Awareness in Biological Sciences; Oncology Information Service; and Cumulative Index to Nursing and Allied Health Literature (CINAHL).

"The duration of action of mivacurium defines a new class of non-depolarizing neuromuscular blocking drugs."p.397

Caldwell JE, Heier T, Kitts JB, Lynam DP, Fahey MR, Miller RD.
Comparison of the neuromuscular block induced by mivacurium,
suxamethonium or atracurium during nitrous oxide-fentanyl anaesthesia.
***Br J Anaesth*. 1989;63:393-399.**

Please see brief summaries for **M**IVACRON® (mivacurium chloride) and Tracrium® (atracurium besylate) following this ad.

MIVACRON®

The first and only shor

Duration of action and spontaneous recovery profile approximately one-third to one-half that of intermediate agents such as atracurium or vecuronium

Initial dose 0.15 mg/kg

Profound neuromuscular block

Recommended initial adult dose

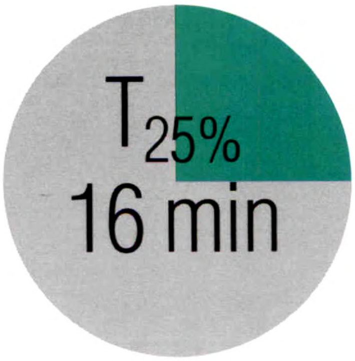
The recommended initial adult bolus dose of 0.15 mg/kg (administered over 5 to 15 seconds) provides profound neuromuscular block.

Intubation 2.5 min

Generally good to excellent intubating conditions

Useful for routine intubation

MIVACRON provides generally good to excellent intubating conditions in 2.5 minutes at a dose of 0.15 mg/kg. Succinylcholine remains the drug of choice for rapid sequence intubation.



Short duration of action

Well-suited for short procedures

Duration of clinically effective block (time to 25% recovery of T_1) following injection of 0.15 mg/kg is 16 minutes, making **M**IVACRON excellent for short procedures.[1]

from Burroughs Wellcome Co.

acting nondepolarizer

Reduce spontaneous recovery time by up to 50% *vs* vecuronium

	Duration of continuous infusion (min)	Recovery times (min) Off-25%*	25-75%	5-95%
MIVACRON (n=25)	**86.2±5.6**	**5.7±0.3**	**6.4±0.2**	**13.6±0.6**
vecuronium (n=18)	96.8±6.6	12.7±1.3[†]	13.8±0.9[‡]	32.0±1.2[‡§]
atracurium (n=22)	91.3±2.9	12.5±0.6[†]	10.9±0.3[†]	26.6±0.4[†]

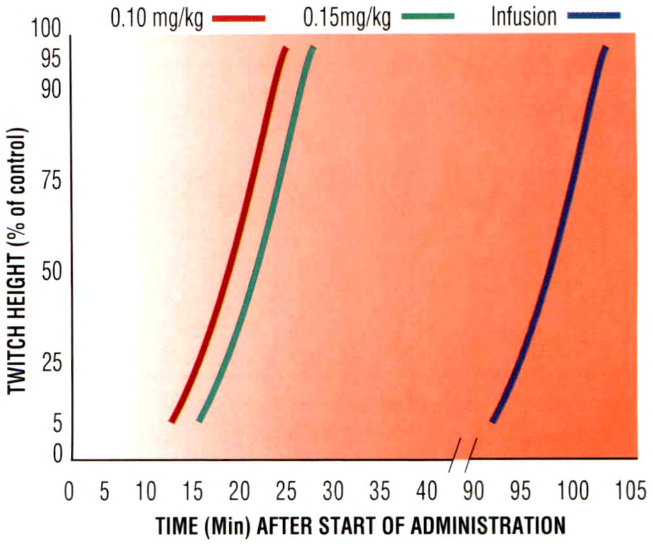
Adapted from Ali et al, p. 544.[2] *Time from discontinuation of infusion to 25% recovery. [†]P<0.01 atracurium or vecuronium vs **M**IVACRON; [‡]P<0.001 vecuronium vs **M**IVACRON; [§]P<0.05 vecuronium vs atracurium.

Noncumulative

Continuous infusion of **M**IVACRON for up to 2.5 hours is not associated with the development of tachyphylaxis or cumulative neuromuscular blocking effects in ASA Physical Status I-II patients. Steady-state levels of block are rapidly achieved with minimal adjustment to the infusion rate. Limited data are available on **M**IVACRON (a mixture of three isomers) for infusions longer than 2.5 hours.

Savarese et al found...

Fast recovery following bolus or infusion



Adapted from Savarese et al, p. 727.[3]

MIVACRON® Injection 2 mg/mL

(mivacurium chloride)

Short duration, fast recovery

Please see brief summaries for **M**IVACRON® (mivacurium chloride) and Tracrium® (atracurium besylate) following this ad.

MIVACRON®

Up to half the duration

Excellent cardiovascular profile at recommended doses

MIVACRON Initial Dose* (mg/kg)	% of patients with ≥30% change			
	MAP		HR	
	↓	↑	↓	↑
0.07 to 0.10	0%	2%	0%	0%
0.15	4%	4%	4%	2%
0.20†	30%	0%	0%	8%
0.25†	39%	2%	0%	14%

*During opioid/N_2O/O_2 anesthesia.

†Experimental dose, in excess of the maximum recommended dose of 0.15 mg/kg.

Minimal CV effects

At the recommended initial dose of 0.15 mg/kg, cardiovascular response to **M**IVACRON is minimal. Higher doses may produce effects associated with histamine release and may result in a decrease in blood pressure in some individuals. The incidence and magnitude of these hemodynamic changes are related to size of the dose and speed of the injection. In patients with clinically significant CV disease, the initial dose of **M**IVACRON should be administered over 60 seconds.

Metabolized by plasma cholinesterase

Like succinylcholine, **M**IVACRON should be used with caution in patients with reduced plasma cholinesterase activity. In patients heterozygous for the atypical plasma cholinesterase gene, clinically effective duration may be prolonged by approximately 10 minutes. Homozygous patients (1 in 2500) are *extremely sensitive* to **M**IVACRON. **M**IVACRON should be used with great caution, if at all, in homozygous patients.

However, unlike succinylcholine, once recovery has begun, **M**IVACRON can be reversed with conventional doses of neostigmine.

Individualization of dosages

- Significant CV disease
- Obesity
- Renal or hepatic disease
- History suggesting greater sensitivity to release of histamine or related mediators

from Burroughs Wellcome Co.

half the recovery time

A nondepolarizing alternative to succinylcholine for elective outpatient surgery

	n	Time to max. block (min)*	Time to recovery of T_1=10% (min)*
succinylcholine 1.0 mg/kg	9	1.1±0.2	7.7±1.4
MIVACRON 0.15 mg/kg	8	**2.5**±0.9	**15.6**±3.4

MIVACRON® INJECTION
MIVACRON® PREMIXED INFUSION
(MIVACURIUM CHLORIDE)

Brief Summary

This drug should be administered only by adequately trained individuals familiar with its actions, characteristics, and hazards.

INDICATIONS AND USAGE: MIVACRON is a short-acting neuromuscular blocking agent indicated for inpatients and outpatients, as an adjunct to general anesthesia, to facilitate tracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation.

CONTRAINDICATIONS: MIVACRON is contraindicated in patients known to have an allergic hypersensitivity to mivacurium chloride or other benzylisoquinolinium agents, as manifested by reactions such as urticaria or severe respiratory distress or hypotension. Use of MIVACRON from multidose vials is contraindicated in patients with a known allergy to benzyl alcohol.

WARNINGS: MIVACRON SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH THE DRUG'S ACTIONS AND THE POSSIBLE COMPLICATIONS OF ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS PERSONNEL AND FACILITIES FOR RESUSCITATION AND LIFE SUPPORT (TRACHEAL INTUBATION, ARTIFICIAL VENTILATION, OXYGEN THERAPY), AND AN ANTAGONIST OF MIVACRON ARE IMMEDIATELY AVAILABLE. IT IS RECOMMENDED THAT A PERIPHERAL NERVE STIMULATOR BE USED TO MEASURE NEUROMUSCULAR FUNCTION DURING THE ADMINISTRATION OF MIVACRON IN ORDER TO MONITOR DRUG EFFECT, DETERMINE THE NEED FOR ADDITIONAL DRUG, AND CONFIRM RECOVERY FROM NEUROMUSCULAR BLOCK.

MIVACRON HAS NO KNOWN EFFECT ON CONSCIOUSNESS, PAIN THRESHOLD, OR CEREBRATION. TO AVOID DISTRESS TO THE PATIENT, NEUROMUSCULAR BLOCK SHOULD NOT BE INDUCED BEFORE UNCONSCIOUSNESS.

MIVACRON IS METABOLIZED BY PLASMA CHOLINESTERASE AND SHOULD BE USED WITH GREAT CAUTION, IF AT ALL, IN PATIENTS KNOWN TO BE OR SUSPECTED OF BEING HOMOZYGOUS FOR THE ATYPICAL PLASMA CHOLINESTERASE GENE.

MIVACRON Injection and MIVACRON Premixed Infusion are acidic (pH 3.5 to 5.0) and may not be compatible with alkaline solutions having a pH greater than 8.5 (*e.g.*, barbiturate solutions).

PRECAUTIONS:

General: Although MIVACRON (a mixture of three stereoisomers) is not a potent histamine releaser, the possibility of substantial histamine release must be considered. Release of histamine is related to the dose and speed of injection.

Caution should be exercised in administering MIVACRON to patients with clinically significant cardiovascular disease and patients with any history suggesting a greater sensitivity to the release of histamine or related mediators (*e.g.*, asthma). In such patients, the initial dose of MIVACRON should be 0.15 mg/kg or less, administered over 60 seconds; assurance of adequate hydration and careful monitoring of hemodynamic status are important (see **Hemodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY).

Obese patients may be more likely to experience clinically significant transient decreases in MAP than non-obese patients when the dose of MIVACRON is based on actual rather than ideal body weight. Therefore, in obese patients, the initial dose should be determined using the patient's ideal body weight (see **Hemodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY).

Recommended doses of MIVACRON have no clinically significant effects on heart rate; therefore, MIVACRON will not counteract the bradycardia produced by many anesthetic agents or by vagal stimulation.

Neuromuscular blocking agents may have a profound effect in patients with neuromuscular diseases (*e.g.*, myasthenia gravis and the myasthenic syndrome). In these and other conditions in which prolonged neuromuscular block is a possibility (*e.g.*, carcinomatosis), the use of a peripheral nerve stimulator and a dose of not more than 0.015–0.020 mg/kg MIVACRON is recommended to assess the level of neuromuscular block and to monitor dosage requirements (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

MIVACRON has not been studied in patients with burns. Resistance to nondepolarizing neuromuscular blocking agents may develop in patients with burns, depending upon the time elapsed since the injury and the size of the burn. Patients with burns may have reduced plasma cholinesterase activity which may offset this resistance (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

Acid-base and/or serum electrolyte abnormalities may potentiate or antagonize the action of neuromuscular blocking agents. The action of neuromuscular blocking agents may be enhanced by magnesium salts administered for the management of toxemia of pregnancy (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

No data are available to support the use of MIVACRON by intramuscular injection.

Renal and Hepatic Disease: The possibility of prolonged neuromuscular block must be considered when MIVACRON is used in patients with renal or hepatic disease (see **Pharmacokinetics** subsection of CLINICAL PHARMACOLOGY). Most patients with chronic hepatic disease such as hepatitis, liver abscess, and cirrhosis of the liver exhibit a marked reduction in plasma cholinesterase activity. Patients with acute or chronic renal disease may also show a reduction in plasma cholinesterase activity (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

Reduced Plasma Cholinesterase Activity: The possibility of prolonged neuromuscular block following administration of MIVACRON must be considered in patients with reduced plasma cholinesterase (pseudocholinesterase) activity.

Plasma cholinesterase activity may be diminished in the presence of genetic abnormalities of plasma cholinesterase (*e.g.*, patients heterozygous or homozygous for the atypical plasma cholinesterase gene), pregnancy, liver or kidney disease, malignant tumors, infections, burns, anemia, decompensated heart disease, peptic ulcer, or myxedema. Plasma cholinesterase activity may also be diminished by chronic administration of oral contraceptives, glucocorticoids, or certain monoamine oxidase inhibitors and by irreversible inhibitors of plasma cholinesterase (*e.g.*, organophosphate insecticides, echothiophate, and certain antineoplastic drugs).

MIVACRON has been used safely in patients heterozygous for the atypical plasma cholinesterase gene. At doses of 0.10 to 0.20 mg/kg MIVACRON, the clinically effective duration of action was 8 to 11 minutes longer in patients heterozygous for the atypical gene than in genotypically normal patients.

As with succinylcholine, patients homozygous for the atypical plasma cholinesterase gene (1 in 2500 patients) are extremely sensitive to the neuromuscular blocking effect of MIVACRON. In three such adult patients, a small dose of 0.03 mg/kg (approximately the $ED_{10\text{-}20}$ in genotypically normal patients) produced complete neuromuscular block for 26 to 128 minutes. Once spontaneous recovery had begun, neuromuscular block in these patients was antagonized with conventional doses of neostigmine. One adult patient, who was homozygous for the atypical plasma cholinesterase gene, received a dose of 0.18 mg/kg MIVACRON and exhibited complete neuromuscular block for about 4 hours. Response to post-tetanic stimulation was present after 4 hours, all four responses to train-of-four stimulation were present after 6 hours, and the patient was extubated after 8 hour Reversal was not attempted in this patient.

Malignant Hyperthermia (MH): In a study of MH-susceptible pigs, MIVACRON did not trigger MI MIVACRON has not been studied in MH-susceptible patients. Because MH can develop in the absen of established triggering agents, the clinician should be prepared to recognize and treat MH in ar patient undergoing general anesthesia.

Long-Term Use in the Intensive Care Unit (ICU): No data are available on the long-term use MIVACRON in patients undergoing mechanical ventilation in the ICU.

Drug Interactions: Although MIVACRON (a mixture of three stereoisomers) has been administere safely following succinylcholine-facilitated tracheal intubation, the interaction between the stereois mers in MIVACRON and succinylcholine has not been systematically studied. Prior administrati of succinylcholine can potentiate the neuromuscular blocking effects of nondepolarizing agents. Eviden of spontaneous recovery from succinylcholine should be observed before the administration MIVACRON.

The use of MIVACRON before succinylcholine to attenuate some of the side effects of succinylcholin has not been studied.

There are no clinical data on the use of MIVACRON with other nondepolarizing neuromuscular bloc ing agents.

Isoflurane and enflurane (administered with nitrous oxide/oxygen to achieve 1.25 MAC) decreas the ED_{50} of MIVACRON by as much as 25% (see **Pharmacodynamics** and **Individualization** **Dosages** subsections of CLINICAL PHARMACOLOGY). These agents may also prolong the cli ically effective duration of action and decrease the average infusion requirement of MIVACRON as much as 35% to 40%. A greater potentiation of the neuromuscular blocking effects of th stereoisomers in MIVACRON may be expected with higher concentrations of enflurane or isofluran Halothane has little or no effect on the ED_{50}, but may prolong the duration of action and decreas the average infusion requirement by as much as 20%.

Other drugs which may enhance the neuromuscular blocking action of nondepolarizing agents suc as the stereoisomers in MIVACRON include certain antibiotics (*e.g.*, aminoglycosides, tetracycline bacitracin, polymyxins, lincomycin, clindamycin, colistin, and sodium colistimethate), magnesiu salts, lithium, local anesthetics, procainamide, and quinidine. Drugs that may enhance the neur muscular blocking effects of mivacurium by a reduction in plasma cholinesterase activity include chro ic administration of oral contraceptives, glucocorticoids, or certain monoamine oxidase inhibito and by irreversible inhibitors of plasma cholinesterase (see **Reduced Plasma Cholinesterase Activit** subsection of PRECAUTIONS).

Resistance to the neuromuscular blocking action of nondepolarizing neuromuscular blockin agents has been demonstrated in patients chronically administered phenytoin or carbamazepin While the effects of chronic phenytoin or carbamazepine therapy on the action of the stereoisomer in MIVACRON are unknown, slightly shorter durations of neuromuscular block may be anticipate and infusion rate requirements may be higher.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenesis and fertility studie have not been performed. MIVACRON was evaluated in a battery of four short-term mutagenici tests. It was non-mutagenic in the Ames Salmonella assay, the mouse lymphoma assay, th human lymphocyte assay, and the *in vivo* rat bone marrow cytogenetic assay.

Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Teratology testing in nonventilate pregnant rats and mice treated subcutaneously with maximum subparalyzing doses of MIVACRO revealed no maternal or fetal toxicity or teratogenic effects. There are no adequate and wel controlled studies of MIVACRON in pregnant women. Because animal studies are not always pr dictive of human response, and the doses used were subparalyzing, MIVACRON should be use during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Labor and Delivery: The use of MIVACRON during labor, vaginal delivery, or cesarean section h not been studied in humans and it is not known whether MIVACRON administered to the mother h effects on the fetus. Doses of 0.08 and 0.20 mg/kg MIVACRON given to female beagles undergoi cesarean section resulted in negligible levels of the stereoisomers in MIVACRON in umbilical ve sel blood of neonates and no deleterious effects on the puppies.

Nursing Mothers: It is not known whether any of the stereoisomers of mivacurium are excreted human milk. Because many drugs are excreted in human milk, caution should be exercised followi administration of MIVACRON to a nursing woman.

Pediatric Use: MIVACRON has not been studied in children below the age of 2 years (see CLI ICAL PHARMACOLOGY and DOSAGE AND ADMINISTRATION for clinical experience and re ommendations for use in children 2 to 12 years of age).

Geriatric Use: MIVACRON was safely administered during clinical trials to 64 elderly (≥65 year patients, including 31 patients with significant cardiovascular disease (see **General** subsection PRECAUTIONS). The duration of neuromuscular block may be slightly longer in elderly patients th in young adult patients (see CLINICAL PHARMACOLOGY).

ADVERSE REACTIONS:

Observed in Clinical Trials: MIVACRON (a mixture of three stereoisomers) was well tolerated d ing extensive clinical trials in inpatients and outpatients. Prolonged neuromuscular block, which an important adverse experience associated with neuromuscular blocking agents as a class, w reported as an adverse experience in 3 of 2074 patients administered MIVACRON. The most co monly reported adverse experience following the administration of MIVACRON was transie dose-dependent cutaneous flushing about the face, neck, and/or chest. Flushing was most frequen noted after the initial dose of MIVACRON and was reported in about 20% of adult patients who receiv the recommended dose of 0.15 mg/kg MIVACRON over 5 to 15 seconds. When present, flushi typically began within 1 to 2 minutes after the dose of MIVACRON and lasted for 3 to 5 minutes. 60 patients who experienced flushing after 0.15 mg/kg MIVACRON, one patient also experienc mild hypotension that was not treated, and one patient experienced moderate wheezing that w successfully treated.

Overall, hypotension was infrequently reported as an adverse experience in the clinical trials MIVACRON. None of the 397 adults or 63 children who received recommended doses was treat for a decrease in blood pressure associated with the administration of MIVACRON. Above the re ommended dosage range, 1% to 2% of healthy adults given ≥0.20 mg/kg over 5 to 15 seconds a 2% to 4% of cardiac surgery patients given ≥0.20 mg/kg over 60 seconds were treated f decreases in blood pressure associated with the administration of MIVACRON.

The following adverse experiences were reported in patients administered MIVACRON (all even judged by investigators during the clinical trials to have a possible causal relationship):

Incidence Greater Than 1% -

Cardiovascular:	Flushing (15%)

Incidence Less Than 1% -

Cardiovascular:	Hypotension, Tachycardia, Bradycardia, Cardiac Arrhythmia, Phlebiti
Respiratory:	Bronchospasm, Wheezing, Hypoxemia
Dermatological:	Rash, Urticaria, Erythema, Injection Site Reaction
Nonspecific:	Prolonged Drug Effect
Neurologic:	Dizziness
Musculoskeletal:	Muscle Spasms

OVERDOSAGE: Overdosage with neuromuscular blocking agents may result in neuromuscular blo beyond the time needed for surgery and anesthesia. The primary treatment is maintenance of a pate airway and controlled ventilation until recovery of normal neuromuscular function is assured. Once evidence of recovery from neuromuscular block is observed, further recovery may be facilitated by administration of an anticholinesterase agent (*e.g.*, neostigmine, edrophonium) in conjunction with an appropriate anticholinergic agent. (see **Antagonism of Neuromuscular Block**). Overdosage may increase the risk of hemodynamic side effects, especially decreases in blood pressure. If needed, cardiovascular support may be provided by proper positioning of the patient, fluid administration, and/or vasopressor agent administration.

Antagonism of Neuromuscular Block:

ANTAGONISTS (SUCH AS NEOSTIGMINE) SHOULD NOT BE ADMINISTERED WHEN COMPLETE NEUROMUSCULAR BLOCK IS EVIDENT OR SUSPECTED. THE USE OF A PERIPHERAL NERVE STIMULATOR TO EVALUATE RECOVERY AND ANTAGONISM OF NEUROMUSCULAR BLOCK IS RECOMMENDED.

Administration of 0.030 to 0.064 mg/kg neostigmine or 0.5 mg/kg edrophonium at approximately 10% recovery from neuromuscular block (range: 1 to 15) produced 95% recovery of the muscle twitch response and a T_4/T_1 ratio ≥75% in about 10 minutes. The times from 25% recovery of the muscle twitch response to T_4/T_1 ratio ≥75% following these doses of antagonists averaged about 7 to 9 minutes. In comparison, average times for spontaneous recovery from 25% to T_4/T_1 ≥75% were 12 to 13 minutes.

Patients administered antagonists should be evaluated for adequate clinical evidence of antagonism, *e.g.*, 5-second head lift and grip strength. Ventilation must be supported until no longer required. Antagonism may be delayed in the presence of debilitation, carcinomatosis, and the concomitant use of certain broad spectrum antibiotics, or anesthetic agents and other drugs which enhance neuromuscular block or separately cause respiratory depression (see **Drug Interactions** subsection of PRECAUTIONS). Under such circumstances the management is the same as that of prolonged neuromuscular block (see OVERDOSAGE).

DOSAGE AND ADMINISTRATION: MIVACRON SHOULD ONLY BE ADMINISTERED INTRAVENOUSLY.

The dosage information provided below is intended as a guide only. Doses of MIVACRON should be individualized (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY). Factors that may warrant dosage adjustment include but may not be limited to: the presence of significant kidney, liver, or cardiovascular disease, obesity (patients weighing ≥30% more than ideal body weight for height), asthma, reduction in plasma cholinesterase activity, and the presence of inhalational anesthetic agents. The use of a peripheral nerve stimulator will permit the most advantageous use of MIVACRON, minimize the possibility of overdosage or underdosage, and assist in the evaluation of recovery.

Adults:

Initial Doses:

A dose of 0.15 mg/kg MIVACRON administered over 5 to 15 seconds is recommended for facilitation of tracheal intubation for most patients. When administered as a component of a thiopental/opioid/nitrous oxide/oxygen induction-intubation technique, 0.15 mg/kg (2 x ED_{95}) MIVACRON produces generally good-to-excellent conditions for tracheal intubation in 2.5 minutes. Lower doses of MIVACRON may result in a longer time for development of satisfactory intubation conditions. Administration of MIVACRON doses above the recommended range (≥0.20 mg/kg) is associated with the development of transient decreases in blood pressure in some patients (see CLINICAL PHARMACOLOGY and ADVERSE REACTIONS).

STORAGE: Store MIVACRON Injection at room temperature of 15° to 25°C (59° to 77°F). Avoid exposure to direct ultraviolet light. DO NOT FREEZE.

Recommended storage for MIVACRON Premixed Infusion is room temperature (15° to 25°C/59° to 77°F). Avoid excessive heat. Avoid exposure to direct ultraviolet light. Protect from freezing.

TRACRIUM® INJECTION

(atracurium besylate)

Brief Summary

This drug should be used only by adequately trained individuals familiar with its actions, characteristics, and hazards.

INDICATIONS AND USAGE: Tracrium is indicated, as an adjunct to general anesthesia, to facilitate endotracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation.

CONTRAINDICATIONS: Tracrium is contraindicated in patients known to have a hypersensitivity to it.

WARNINGS: TRACRIUM SHOULD BE USED ONLY BY THOSE SKILLED IN AIRWAY MANAGEMENT AND RESPIRATORY SUPPORT. EQUIPMENT AND PERSONNEL MUST BE IMMEDIATELY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND SUPPORT OF VENTILATION, INCLUDING ADMINISTRATION OF POSITIVE PRESSURE OXYGEN. ADEQUACY OF RESPIRATION MUST BE ASSURED THROUGH ASSISTED OR CONTROLLED VENTILATION. ANTICHOLINESTERASE REVERSAL AGENTS SHOULD BE IMMEDIATELY AVAILABLE. DO NOT GIVE TRACRIUM BY INTRAMUSCULAR ADMINISTRATION. Tracrium has no known effect on consciousness, pain threshold, or cerebration. It should be used only with adequate anesthesia. Tracrium Injection, which has an acid pH, should not be mixed with alkaline solutions (e.g., barbiturate solutions) in the same syringe or administered simultaneously during intravenous infusion through the same needle. Depending on the resultant pH of such mixtures, Tracrium may be inactivated and a free acid may be precipitated. Tracrium Injection 10 mL multiple dose vials contain benzyl alcohol. Benzyl alcohol has been associated with an increased incidence of neurological and other complications in newborn infants which are sometimes fatal. Tracrium Injection 5 mL single use vials do not contain benzyl alcohol.

PRECAUTIONS: General: Although Tracrium is a less potent histamine releaser than d-tubocurarine or metocurine, the possibility of substantial histamine release in sensitive individuals must be considered. Special caution should be exercised in administering Tracrium to patients in whom substantial histamine release would be especially hazardous (e.g., patients with clinically significant cardiovascular disease) and in patients with any history (e.g., severe anaphylactoid reactions or asthma) suggesting a greater risk of histamine release. In these patients, the recommended initial Tracrium dose is lower (0.3 to 0.4 mg/kg) than for other patients and should be administered slowly or in divided doses over one minute. Since Tracrium has no clinically significant effects on heart rate in the recommended dosage range, it will not counteract the bradycardia produced by many anesthetic agents or vagal stimulation. As a result, bradycardia during anesthesia may be more common with Tracrium than with other muscle relaxants. Tracrium may have profound effects in patients with myasthenia gravis, Eaton-Lambert syndrome, or other neuromuscular diseases in which potentiation of nondepolarizing agents has been noted. The use of a peripheral nerve stimulator is especially important for assessing neuromuscular blockade in these patients. Similar precautions should be taken in patients with severe electrolyte disorders or carcinomatosis. Multiple factors in anesthesia practice are suspected of triggering malignant hyperthermia (MH), a potentially fatal hypermetabolic state of skeletal muscle. Halogenated anesthetic agents and succinylcholine are recognized as the principal pharmacologic triggering agents in MH-susceptible patients; however, since MH can develop in the absence of established triggering agents, the clinician should be prepared to recognize and treat MH in any patient scheduled for general anesthesia. Reports of MH have been rare in cases in which Tracrium has been used. In studies of MH-susceptible animals (swine) and in a clinical study of MH-susceptible patients, Tracrium did not trigger this syndrome. Resistance to nondepolarizing neuromuscular blocking agents may develop in burn patients. Increased doses of nondepolarizing muscle relaxants may be required in burn patients and are dependent on the time elapsed since the burn injury and the size of the burn. The safety of Tracrium has not been established in patients with bronchial asthma. **Long-Term Use in Intensive Care Unit (ICU):** Tracrium has been used to facilitate mechanical ventilation in ICU patients. When there is a need for long-term mechanical ventilation, the benefits to risk ratio of neuromuscular blockade must be considered. There is only limited information on the efficacy and safety of Tracrium administered by long-term (days to weeks) intravenous infusion to facilitate mechanical ventilation in intensive care facilities. For Tracrium, as with other neuromuscular blocking agents used in intensive care facilities, available evidence suggests that there is wide interpatient variability in dosage requirements and that these requirements may change with time. Limited data suggest that Tracrium infusion requirements may increase with prolonged administration in the ICU. As with other neuromuscular blocking agents, little information is available on the plasma levels or clinical consequences of atracurium metabolites following long-term (days to weeks) infusion of Tracrium in the intensive care unit setting. One metabolite of atracurium, laudanosine, when administered alone to laboratory animals, has been associated with cerebral excitatory effects. Physiological effects of laudanosine in humans have not been demonstrated. The effects of hemodialysis, hemoperfusion and hemofiltration on plasma levels of atracurium and its metabolites are unknown. **Drug Interactions:** Drugs which may enhance neuromuscular blocking action of Tracrium include: enflurane; isoflurane; halothane; certain antibiotics, especially the aminoglycosides and polymyxins; lithium; magnesium salts; procainamide; and quinidine. If other muscle relaxants are used during the same procedure, the possibility of a synergistic or antagonist effect should be considered. The prior administration of succinylcholine does not enhance the duration, but quickens the onset and may increase the depth, of neuromuscular blockade induced by Tracrium. Tracrium should not be administered until a patient has recovered from succinylcholine-induced neuromuscular blockade. **Carcinogenesis, Mutagenesis, Impairment of Fertility:** A positive response was observed in the mouse lymphoma assay under conditions which killed over 80% of the treated cells. A far weaker response was observed in the presence of metabolic activation at concentrations which also killed over 80% of the treated cells. **Pregnancy:** ***Teratogenic Effects:*** Pregnancy Category C. Tracrium has been shown to be potentially teratogenic in rabbits, when given in doses up to approximately one-half the human dose. There are no adequate and well-controlled studies in pregnant women. Tracrium should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Labor and Delivery:** It is not known whether muscle relaxants administered during vaginal delivery have immediate or delayed adverse effects on the fetus or increase the likelihood that resuscitation of the newborn will be necessary. The possibility that forceps delivery will be necessary may increase. Tracrium (0.3 mg/kg) has been administered to 26 pregnant women during delivery by cesarean section. No harmful effects were attributable to Tracrium in any of the newborn infants, although small amounts of Tracrium were shown to cross the placental barrier. The possibility of respiratory depression in the newborn infant should always be considered following cesarean section during which a neuromuscular blocking agent has been administered. In patients receiving magnesium sulfate, the reversal of neuromuscular blockade may be unsatisfactory and Tracrium dose should be lowered as indicated. **Nursing Mothers:** It is not known whether this drug is excreted in human milk. Caution should be exercised when Tracrium is administered to a nursing woman. **Pediatric Use:** Safety and effectiveness in children below the age of 1 month have not been established.

ADVERSE REACTIONS: Observed in Controlled Clinical Studies: Tracrium produced few adverse reactions during extensive clinical trials. Most were suggestive of histamine release (see Precautions Section). The overall incidence rate for clinically important adverse reactions was 7/875 or 0.8%. Most adverse reactions were of little clinical significance unless they were associated with significant hemodynamic changes. Substantial vital sign changes greater than or equal to 30% observed in 530 patients, without cardiovascular disease, were as follows: in those patients given the recommended initial dosage range of 0.31 to 0.50 mg/kg of Tracrium, mean arterial pressure increased in 2.8% and decreased in 2.1% of patients while the heart rate increased in 2.8% of these patients. At doses of ≥ 0.60 mg/kg, 14.3% of the studied patients had a decrease in mean arterial pressure while 4.8% had an increase in heart rate. At doses ≤ 0.30 mg/kg, mean arterial pressure increased in 1.9% and decreased in 1.1% of patients, while heart rate increased in 1.6% and decreased in 0.8% of these patients. **Observed in Clinical Practice:** Based on clinical experience in the U.S. and the United Kingdom of approximately 3 million patients given Tracrium the following adverse reactions are among the most frequently reported: *General:* allergic reactions (anaphylactic or anaphylactoid) which, in rare instances, were severe (e.g., cardiac arrest); *Musculoskeletal:* inadequate, prolonged block; *Cardiovascular:* hypotension, vasodilatation (flushing), tachycardia, bradycardia; *Respiratory:* dyspnea, bronchospasm, laryngospasm; *Integumentary:* rash, urticaria, injection site reaction.

STORAGE: Tracrium Injection should be refrigerated at 2° to 8° C (36° to 46° F) to preserve potency. DO NOT FREEZE. Upon removal from refrigeration to room temperature storage conditions (25°C/77°F), use Tracrium Injection within 14 days even if rerefrigerated.

OHIO
Anesthesiologist, University Hospitals. Must be at least board eligible. Equal Opportunity, Affirmative Action Employer. Send curriculum vitae to Helmut F. Cascorbi, MD, PhD, Professor and Chairman, Department of Anesthesiology, University Hospitals of Cleveland, 2074 Abington Road, Cleveland, OH 44106.

701E/L

ILLINOIS: ANESTHESIOLOGIST
To join congenial group of MDs/CRNAs expanding to provide anesthesia coverage for only hospital in city since recent merger. No open heart or neurosurgery. Environment conducive to family living, variety of schools, recreation. Good opportunity with stable future. City located in east central Illinois with population of approximately 40,000 (35-mile radius service area with 126,126 population). Within driving distance of Chicago and Indianapolis. Please send CV to Box 887D/L.

887D/L

EASTERN PENNSYLVANIA
Hospital needs two board-certified/board-eligible anesthesiologists to join a fee-for-service group in a 225-bed progressive hospital. Applicants must be a PGIV preferrably with pain management, residency rotation. Reply to Box 888D/I.

888D/I

CARDIOVASCULAR FELLOWSHIP OPPORTUNITY
The Department of Anesthesiology and Critical Care Medicine at the University of New Mexico School of Medicine has openings at the CA-4 level for advanced training in cardiovascular anesthesiology. The fellowship is a 2-year comprehensive program designed to train the fellow for a career in cardiovascular anesthesiology. Research in cardiovascular physiology and anesthesia, provision of clinical care for complex adult and pediatric cases, participation in conference, and teaching responsibilities are part of the fellowship experience. Interested individuals should send CV or contact Jorge A. Estrin, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of New Mexico School of Medicine, Albuquerque, NM 83131-5216, (505) 272-2610, FAX (505) 277-1300. The University of New Mexico is an Equal Opportunity/Affirmative Action Employer.

912F/L

THE UNIVERSITY OF NEW MEXICO
Department of Anesthesiology and Critical Care Medicine has immediate faculty positions at the Instructor, Assistant Professor, Associate Professor, and Professor levels for candidates with experience in cardiac, obstetric, neurosurgical, and pediatric anesthesia and critical care medicine. Responsibilities include the teaching of medical students and residents and the provision of clinical care in a busy tertiary referral center. Opportunities to pursue research interests will be provided. It is expected that candidates who apply for CCM positions will have or be eligible for subspecialty certification. Qualified candidates should send CV or contact Jorge A. Estrin, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of New Mexico School of Medicine, Albuquerque, NM 87131-5216, (505) 272-2610, FAX (505) 277-1300. The University of New Mexico is an Equal Opportunity/Affirmative Action Employer.

913F/L

Immediate opening for a BC/BE anesthesiologist to join six MD anesthesiologists in a fee-for-service practice in a 350-bed hospital in a retirement community in Sun City, Arizona. No OB, open heart, trauma, or pediatrics. Send replies to Box 923GHI.

923GHI

NORTH EAST, INDIANA
Group seeking BC/BE anesthesiologists to join large MD-only group. All types of anesthesia provided, including OH and OB. Immediate opening. Early partnership offered. Send CV to Box 926G/I.

926G/I

The Department of Anesthesiology at Duke University Medical Center invites qualified full-time faculty to apply for positions in the following categories: NEUROANESTHESIA—We are seeking an academic faculty candidate trained in neurosurgical anesthesia to lead a developing neuroanesthesia section as chief of the section. This opportunity requires a candidate with a primary interest in investigative research and teaching in addition to clinical expertise in all aspects of neuroanesthesiology including an interest in the development of a neurological intensive care unit. A new spacious neuroscience facility at Duke fosters interdisciplinary relationships with neuropharmacology, neuroradiology, neurobiology, and neurology. The neuroscience program at Duke University is one of the five developing centers of excellence at this nationally prominent university. CRITICAL CARE MEDICINE—We are seeking individuals who are ABA certified or board eligible in critical care medicine, for the position of Co-Director, SICU at the Durham VA Medical Center (where a new ICU tower is under construction) and/or as critical care faculty in the SICU at Duke University Medical Center. Faculty will play an essential role in the coordination of care in a multidisciplinary consulting service and in the development of an interdisciplinary Critical Care Fellowship program. GENERAL INTERESTS AND CLINICAL PHARMACOLOGY—We have positions for starting academicians whose subspecialty interests are broad or undefined, but who desire to begin an academic career in a setting with an emphasis on clinical research in pharmacology and epidemiology as it relates to the practice of anesthesiology.

Academic titles and compensation for the

CLASSIFIED ADS

Anesthesia & Analgesia makes available classified advertising space for those interested in obtaining positions or wishing to announce meetings, postgraduate courses, or other pertinent events. We require that all advertisements be relevant to the practice of anesthesia and analgesia, and we reserve the right to refuse advertisements that are not relevant.

Specifications. Ads should be typewritten on letterhead stationery; the text should be double-spaced, with the title or key phrase typed in capital letters. Enclose two photocopies with each ad. Display space (minimum ¼ page) is available through Pharmaceutical Media, Inc., 440 Park Avenue South, 14th floor, New York, NY 10016, telephone: (212) 685-5010, FAX: (212) 685-6126.

Rates. Ads cost $1.50 per word per insertion, with a minimum of 20 words. Abbreviations, dates, initials, post office box numbers, telephone numbers, years, and zip codes are considered one word each. There is an additional fee of $18.00 per insertion for box number ads.*

Payment. Full payment or institutional purchase order must accompany the copy for each ad. Ads received without a check or purchase order will be returned. (Make checks payable to Elsevier Science Publishing Company, Inc.)

Deadline. Copy must be received 7 weeks before publication date (i.e., by January 1 for the March issue); multiple-insertion ads are welcome. Ads may run up to 6 months per purchase order/payment. Please specify in which issue(s) your advertisement is to appear.

Send all ad copy, payments, and correspondence to: *Anesthesia & Analgesia*, Classified Ads, Desk Editorial, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

*When responding to a box number ad, include the box number on all correspondence.

above positions will be commensurate with experience and credentials in education, clinical service, and research. Candidates must be board certified or board eligible, and eligible for an unrestricted North Carolina medical license. Please send letter of application and curriculum vitae to J. G. Reves, MD, Box 3094, Duke University Medical Center, Durham, NC 27710. Duke University is an Affirmative Action-Equal Opportunity Employer.

927G/I

LAKE CHAMPLAIN-ADIRONDACK REGION NEW YORK

Growing group seeks a BC/BE anesthesiologist at 410-bed regional referral hospital. Department consists of six anesthesiologists and two CRNAs for 6000 cases/year. No hearts or transplants. Mostly Narkomed 3 machines with H-P Merlin monitors. Plattsburgh is located at the foothills of the Adirondacks and on Lake Champlain, the sixth largest lake in the country. Montreal and Lake Placid region are within 1-hour drive. Excellent public and private schools, state university, affordable real estate, active arts council, and wide variety of recreational activities combine to offer an extraordinary family environment. For details or to view a video of the hospital and community, contact Hannah Hanford, Box 1656, Plattsburgh, NY 12901; (518) 643-2998.

929G/I

CALIFORNIA

University of California, Irvine: Openings for faculty positions in the Department of Anesthesiology. (1) Assistant or associate professor level in the in-residence series. Responsibilities include teaching and research. (2) Clinical instructor and assistant professor level in the clinical series. Responsibilities include teaching and clinical service. Participation in research is highly desirable but not mandatory

Rank and pay commensurate with skills and experience. Faculty will serve at both a tertiary-care university hospital and a VA Medical Center. Candidates must be ABA certified, or in the examination process, and be eligible for a California state license. An Affirmative Action, Equal Opportunity Employer. Address correspondence with references and curriculum vitae to Steven J. Barker, PhD, MD, Chair, Department of Anesthesiology, University of California, Irvine Medical Center, 101 City Drive South, Route 81A, Orange, CA 92668.

930G/L

LOUISIANA STATE UNIVERSITY MEDICAL CENTER—SHREVEPORT

Faculty positions available for board certified/eligible anesthesiologists. Duties include patient care, resident and student teaching, supervision of CRNAs, research, and administrative responsibilities. Faculty rank and salary commensurate with experience. Please send curriculum vitae and names of three references to D. Richard Davis, II, MD, Associate Professor and Chairman, Department of Anesthesiology, LSU Medical Center—Shreveport, 1501 Kings Highway, Shreveport, LA 71130-3932. We are an Equal Opportunity/Affirmative Action Employer.

931G/L

TENNESSEE

Expanding department requires additional anesthesiologists. Full-time positions available at levels of instructor to associate professor with emphasis on teaching, patient care, and clinical research. Prerequisites: (1) meet Tennessee license requirements; (2) ABA diplomat or eligible for ABA examination. All subspecialties needed. Excellent opportunity for anesthesiologists who want an ideal mix of private practice with teaching and clinical research. Send curriculum vitae, bibliography, and the names and addresses of three references to John Zanella, Jr, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of Tennessee, Memphis, 800 Madison Avenue, Memphis, TN 38163. The University of Tennessee is an Equal Opportunity Employer/Affirmative Action Register/Title IX/Section 504 Employer.

934H/J

ANESTHESIOLOGIST

Multispecialty group of 43 physicians adjacent to 165-bed hospital in need of BC/BE anesthesiologist. Located in West Texas City of 80,000 with excellent recreational activities. Salary guarantee with bonus based on production. Send CV to West Texas Medical Associates, 3555 Knickerbocker Road, San Angelo, TX 76904.

936H/A

NEW ORLEANS

Louisiana State University Medical Center, Department of Anesthesiology, is seeking a board-certified anesthesiologist who is interested in directing publications and research. Outstanding opportunities for clinical studies are available. No night call, weekends, or holidays are required. Excellent salary and fringe benefits. Eligibility for Louisiana licensure is prerequisite. Please send curriculum vitae to M. Naraghi, MD, Professor and Chairman, LSU Department of Anesthesiology, 1532 Tulane Avenue, New Orleans, LA 70140. LSUMC is an EEO/AA employer.

937H/A

OLEAN, N.Y.

Anesthesiologist to join expanding group serving busy hospital in the beautiful Southern Tier. Very competitive salary and benefits. School loans may be forgiven. Send CV to Joseph Kehoe, RR 1, Box 363, Clayton, NY 13624 or call (315) 686-2434 for details.

940H/J

CARDIAC ANESTHESIOLOGIST

Albert Einstein Medical Center is a 600-bed, university-affiliated, tertiary-care hospital with a rapidly growing cardiac surgical program. The Division of Cardiac Anesthesia seeks BC/BE individuals who have completed a cardiac fellowship or have significant cardiac experience. The position includes clinical care and teaching responsibilities. Rank and salary commensurate with experience. Send curriculum vitae to Rick Fine, MD, Chairman, Division of Cardiac Anesthesia, Albert Einstein Medical Center, 5501 Old York Road, Philadelphia, PA 19141-3098.

941HI

ILLINOIS

Opening for full or part-time BC/BE anesthesiologist to join group practice with academic affiliation. Eleven physicians and 15 CRNAs, cardiothoracic, neuro, neonatal, and OB. Excellent salary and benefits. Send CV to Sangamon Anesthesiologists, St. John's Hospital, 800 East Carpenter, Springfield, IL 62769. (217) 544-3311 (collect).

942H/J

ANESTHESIOLOGIST — BC/BE — Immediate opening. All specialties including cardiac. Excellent salary leading to early partnership. Send CV to Medical Associates, PO Box 141, Minot, ND 58702. (701) 857-5448; FAX (701) 839-8024.

943H/J

TEXAS

Private practice group is seeking BE/BC anesthesiologist(s) to join new group forming in North Central Texas just minutes from the Dallas/Ft. Worth Metroplex. Excellent starting salary and practice opportunity. Also accepting applications from CRNAs seeking employment. Facility is a 200-bed community hospital involving predominantly orthopedics, general, and ENT cases with obstetrical service starting immediately. Send CV to NTAA, P.O. Box 630652, Iriving, TX 75063-0652.

945HI

PENNSYLVANIA

The ALBERT EINSTEIN MEDICAL CENTER has two faculty positions available. (1) PAIN: To spend 40% of time in pain clinic and additional time on the acute postoperative pain service. Possibility for appointment as Co-Director of Pain Medicine for the right individual. For the individual with special interest in upper extremity regional blockade, there is an opportunity to work with two new hand surgeons. (2) PEDIATRIC: To become a member of a four-person pediatric anesthesia team. About 20% of time will be pediatrics.

For both positions, clinical responsibility is for all types of predominantly adult cases except cardiac. Interest in teaching residents required; interest in research preferred.

The Albert Einstein Medical Center is a modern 600+ bed tertiary hospital, level one trauma center, and a transplant center in Philadelphia. Over 12,000 anesthetics performed annually. All faculty (18) receive full academic appointments at the Temple University School of Medicine. Very competitive salary and benefits. Interested applicants should reply with CV to Jonathan Roth, MD, Department of Anesthesiology, Albert Einstein Medical Center, 5501 Old York Road, Philadelphia, PA 19141. (215) 456-7979.

946HI

MEMORIAL SLOAN-KETTERING CANCER CENTER

Postgraduate Course on "Current Concepts in Cancer and Acute Pain Management," December 10–11, 1992. This course will provide a broad coverage of the management of cancer pain and acute pain for the practicing anesthesiologist. The objective is to exchange information on recent advances, current concepts in diagnosis, and the technical advancement in pain management.

HIGHLIGHTS: State-of-the-art lectures, syllabus, CME credit in Category I.

REGISTRATION: $350.00 for physicians before October 1, 1992; $400.00 for physicians from October 2 to December 9, 1992; $450.00 for ON-SITE registration; $250.00 for 1-day attendance; $200.00 for residents,* fellows,* and nurses (with letter from Program Director*). For more details, please contact: CME office, MSKCC, 1275 York Avenue, New York, NY 10021. (212) 639-6754, (212) 717-3140 FAX.

947HI

PAIN MANAGEMENT TRAINING—ACUTE AND CHRONIC—CA-3 AND FELLOWSHIP POSITIONS

University of Cincinnati Anesthesia Department and the Pain Control Center are seeking applications for Fellowship (preferred) and CA-3 positions in acute and chronic pain management, including cancer pain and pediatric pain management. Chronic benign pain is managed in an interdisciplinary fashion, run by anesthesiologists; program includes inpatient, intensive outpatient, and standard outpatient programs. The Acute Pain Service is aggressive and well accepted, employing all modalities in the management of postoperative and ICU/trauma patients. Opportunities are available for clinical research. Direct inquiries to Donna Benesch, Department of Anesthesia, University of Cincinnati Medical Center, 231 Bethesda Avenue, ML 531, Cincinnati, OH 45267-0531. Phone: (513) 558-6356, FAX: (513) 558-0995.

948H/J

POSTDOCTORAL FELLOWSHIP

Background in clinical medicine or clinical research required for studies with patients with heart disease undergoing surgery. Cardiac function and ischemia assessed with ECG, Holter, and echocardiography monitoring. Working with cardiologists, epidemiologists, and anesthesiologists. Send CV and names of three references to Dennis T. Mangano, PhD, MD, Professor and Vice Chairman, Department of Anesthesia, University of California, San Francisco, 4150 Clement Street (129), San Francisco, CA 94121.

949H/L

FELLOWSHIPS

The Department of Anesthesiology at the University of Alabama at Birmingham offers fellowships for 1–2 years with a 50% to 80% commitment to clinical or bench research with the remaining 20% to 50% commitment to clinical training. Fellowships are available without a research commitment. The fellowships are available in the following areas: (1) *Cardiothoracic Anesthesia*, (2) *Pain Management* (including chronic pain, postoperative pain, pain management of patients with terminal cancer), (3) *Transplantation* (including renal, hepatic, pancreatic, cardiac, and lung), (4) *Neuroanesthesia* (including brain and spinal cord electrophysiological monitoring), (5) *Outpatient Anesthesia*, (6) *Obstetrics*, (7) *Laboratory Research* (pain mechanisms, ischemia-reperfusion injury, nitric oxide, and others). Please send curriculum vitae to Simon Gelman, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of Alabama at Birmingham, 619 South 19th Street, Birmingham AL 35233. An Affirmative Action/Equal Employment Opportunity Employer.

950H/J

CHIEF—CRITICAL CARE DIVISION, ASSOCIATE DIRECTOR—SURGICAL ICU

Department of Anesthesiology, University of Alabama at Birmingham is seeking a board-certified anesthesiologist, certified or eligible in critical care medicine, for Chief—Division of Critical Care and Associate Director—Surgical ICU. Responsibilities include subspecialty resident education in critical care, patient care, research, administration, and recruitment of anesthesiologists-intensivists. Excellent research opportunities. Highly competitive salaries. Contact Simon Gelman, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of Alabama at Birmingham, 619 South 19th Street, Birmingham, AL 35233, (205) 934-4696. An Affirmative Action/Equal Employment Opportunity Employer.

951H/J

CA-IV POSITIONS IN ANESTHESIOLOGY

The Department of Anesthesia at New England Medical Center Hospitals, Boston, Massachusetts (Tufts University) is accepting applications for CA-IV positions in adult cardiac anesthesia. This will be a 6–12-month rotation specializing in all aspects of cardiac anesthesia. Include CV with letter. Reply to Box 952HI.

952HI

OB anesthesiologist sought for large university-affiliated hospital. Approximate 300 deliveries a month with many high risk. In-house neonatologists. Reasonable call schedule with competitive compensation package and partnership after 1 year. Send or fax CV to Barney S. H. Feinstein, MD, Chairman, Department of Anesthesia, Washington Hospital Center, 110 Irving Street, NW, Washington, DC 20010; Fax number (202) 877-5564.

872CEGIK

BC/BE anesthesiologist for a 500-bed tertiary hospital in a Florida coastal city. Immediate opening. Liberal salary and early partnership. Send resume to Box 956I/L.

956I/L

Pain fellowship available for 12 months of formal training beginning January 1, 1993 or July 1993. Multidisciplinary chronic pain service treating a wide spectrum of conditions. Active acute pain service; strong emphasis on regional anesthesia. Excellent hands-on experience; research projects available if desired. Please send CV to Sanford L. Klein, DDS, MD, Chairman, Department of Anesthesia, UMDNJ-Robert Wood Johnson Medical School, 1 Robert Wood Johnson Place, CN 19, New Brunswick, NJ 08903-0019. UMDNJ, NJ's university of the health sciences, is an Affirmative Action/Equal Employment Opportunity Employer, m/f/h/v, and a member of the University Health System of New Jersey.

953IA

Anesthesiologist, DO, board-certified, 25 years' experience, licensed in WA, MI, PA, and MO, presently chairman of 7-man department in general medical hospital, interested in making a change. Reply to Box 954I.

954I

UNIVERSITY OF NORTH CAROLINA AT CHAPEL HILL SCHOOL OF MEDICINE, ANESTHESIOLOGY DEPARTMENT, is seeking qualified applicants for clinical and tenure-track faculty positions. Demonstrated experience in a subspecialty clinical area (e.g., Pain Management, Obstetric, Critical Care Medicine, etc.), teaching experience, emerging research productivity, and proven ability to present research at major medical meetings are desirable. Women and minorities are encouraged to voluntarily identify themselves. Applicants should send a curriculum vitae, a short statement of academic goals, and three letters of reference to Edward Norfleet, MD, Chairman, Anesthesiology Faculty Search Committee, Department of Anesthesiology, CB #7010, 223 Burnett-Womack, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599-7010. The University of North Carolina at Chapel Hill is an Affirmative Action/Equal Opportunity Employer.

955I

BOISE, IDAHO—PAIN MANAGEMENT

MD/CRNA group seeking additional BC/BE anesthesiologist with pain fellowship or extensive pain experience for expanding pain clinic. Growing 250-bed hospital soon to be adding a Cancer Institute and Open Heart program. No OB. Great opportunity in progressive community (130,000) located in the foothills. Excellent for family and all types of year-round recreation. Partnership after 1 year. Please respond to William G. Binegar, MD, 6054 Emerald, Boise, ID 83704-8863.

957I/K

COASTAL NEW JERSEY—ANESTHESIOLOGIST DESIRED

Immediate opening for BC or BE MD/DO to join an expanding group practice of 10 MDAs and 9 CRNAs covering a 500-bed regional medical center composed of two hospitals performing over 9000 anesthetics. All types of anesthesia except OH. Great opportunity for energetic well-trained individual. Unlimited opportunity and outstanding lifestyle in a family-oriented seashore community. Very competitive financial package. Please reply with CV to S. Hernberg, DO, Chairman, Department of Anesthesiology, 1925 Pacific Avenue, Atlantic City, NJ 08401.

958I/K

Anesthesiologist to join group consisting of eight anesthesiologists and two CRNAs. Must be board eligible or board certified. Established PC with many fringe benefits in effect. Send CV to Associated Anesthesiologists of Saginaw, PC, 3121 Davenport, Saginaw, MI 48602 or call (517) 791-2150.

959I/K

ANESTHESIOLOGIST—ST. LOUIS

Diversified Anesthesia Services, Inc., a thriving St. Louis based anesthesia group is seeking a BC/BE anesthesiologist to join the group. We offer an excellent financial package leading to partnership after 2 years. Direct inquiries and curriculum vitae to Sidney Bennett, MD, Department of Anesthesiology, Third Floor, Deaconess Hospital, 6150 Oakland Avenue, St. Louis, MO 63139; (314) 768-3198.

960I

PENNSYLVANIA

Faculty positions are available for board certified or eligible anesthesiologists at the University of Pittsburgh Medical Center. Position level and salary are dependent upon qualifications, with responsibilities including clinical care, teaching, and various aspects of administration and research. EEO/AA Employer. Send credentials to Peter M. Winter, MD, Chairman, Department of Anesthesiology, University of Pittsburgh Medical Center, A-1305 Scaife Hall, Pittsburgh, PA 15261.

961I

WANTED

TWO ACADEMIC ANESTHESIOLOGISTS at the clinical instructor/clinical assistant professor level. Must have an MD degree, completed a 4-year residency in anesthesiology, have documentation in researh fellowship or postgraduate training, and be board certified or board eligible. The positions have an anticipated starting date of January 4, 1993 or later in the academic year. Stipend negotiable and dependent on credentials. Interested parties should forward letter including board status, curriculum vitae, and bibliography to Robert E. Redfern, MD, Search Committee Chairman, Department of Anesthesiology, University of Florida Health Science Center Jacksonville, 655 West 8th Street, Jacksonville, FL 32209. Application recruiting deadline for both positions is October 15, 1992. Equal Employment Opportunity/Affirmative Action Employer.

964I

PHILADELPHIA, PA.

BC/BE anesthesiologist to join physician/CRNA group in a private, university-affiliated, center-city, tertiary-care hospital. No obstetrics, trauma, or pediatrics. Fellowship experience in open heart anesthesia required. Competitive salary, benefits, and potential for partnership is included. Respond with CV to Box 965I/K.

965I/K

DIRECTORSHIP: VIRGINIA BEACH, VIRGINIA

Opportunity for an anesthesiologist with experience in ambulatory surgery to direct a new ambulatory surgery center in coastal Virginia. Join a group of eight anesthesiologists as Medical Director. No call and/no weekends. Salary plus bonus with exceptional benefits/pension plan. Send CV, or call Greg Pilgrim, Jackson and Coker, Inc., 115 Perimeter Center Place, Suite 380 12187, Atlanta, GA 30346; telephone: 1-800-544-1987.

966I

UCSF PEDIATRIC ANESTHESIOLOGY FELLOWSHIP

The Departments of Anesthesia at the University of California, San Francisco and Children's Hospital of Northern California, Oakland, California are jointly offering two 1-year clinical fellowship positions (CA-4) in pediatric anesthesiology beginning *July 1993*. The fellowship will include extensive operating room experience in all pediatric subspecialties in both institutions and critical care medicine exposure for both neonates, older infants, and children. The fellows will spend 6 months in each institution. Send inquiries to Dolores Scholz, Postdoctoral Coordinator, Department of Anesthesia, University of California, San Francisco, Box 0648, San Francisco, CA 94143-0648.

967I/L

ANESTHESIOLOGIST

Department of Anesthesiology at the SUNY Health Science Center in Syracuse, N.Y. is recruiting faculty at the instructor and assistant and associate professor levels. Qualified individuals with a strong academic commitment in all types of anesthesia, critical care, and pain management are sought. SUNY Health Science Center is a tertiary-care center and provides clinical services also to the Syracuse Veterans Administration Hospital. Rank and salary are commensurate with experience. Must be board certified or board eligible and possess a New York State medical license. Please send letter, curriculum vitae, names, addresses, and phone numbers of three references to Enrico M. Camporesi, MD, Professor and Chairman, Department of Anesthesiology, SUNY Health Science Center, Syracuse, NY 13210. The State University of New York Health Science Center is an Equal Opportunity/AA Employer.

968I/K

ANESTHESIOLOGIST/PAIN MANAGEMENT (PORTLAND, OREGON)

Northwest Permanente, P.C., a stable, multispecialty group providing care for 380,000 members of Kaiser Permanente, is seeking a BC/BE anesthesiologist to join a group of 9 anesthesiologists and 27 CRNAs at our 220-bed Sunnyside Medical Center, one of two Kaiser medical centers in the Portland area. Group provides full range of anesthesia services except for open heart.

Special interest: Pain Management, fellowship trained. Join two other trained MDs part-time in a growing Chronic Pain Clinic with dedicated time, clinical procedure-room space, and an OR block for fluoroscopy procedures. The department has ongoing research projects in both pain and anesthesia and is preparing a book manuscript on pain.

Stimulating professional environment, beautiful recreation area with easy access to mountains and beaches. Excellent salary and benefits including paid malpractice, sabbatical, two pension plans, and more. Please forward CV to Fred M. Nomura, MD, Regional Medical Director, NORTHWEST PERMANENTE, P.C., 2701 N.W. Vaughn, Suite 300, Portland, OR 97210-5398. EOE.

969I

UNIVERSARY OF CALIFORNIA, DAVIS—
Assistant Professor/Associate Professor/Full Professor

Department of Anesthesiology, University of California, Davis, Medical Center is recruiting for two (2) faculty positions at all ranks. These positions require experience in teaching and clinical training, as well as clinical research. Both positions require demonstrated experience, training, and certification in (1) Critical Care to join two other faculty covering ICU 2–3 months per year; (2) Transplant; and (3) General Anesthesia. These positions are in the non-tenured track. Rank and salary are commensurate with experience and based on the UCD School of Medicine Faculty Compensation Plan. Must be board certified or board eligible in anesthesiology, and a California medical license is required. Send curriculum vitae, bibliography, copies of publications, and *the names of three (3) references* to: Dennis Fung, MD, Acting Chairman, Department of Anesthesiology, University of California, Davis, 2315 Stockton Boulevard, Room 2304, Sacramento, CA 95817. Positions are open until filled but not later than December 31, 1992. The University of California, Davis is an Equal Opportunity/Affirmative Action Employer with a strong institutional commitment to the achievement of diversity among its faculty and staff. In that spirit, we are particularly interested in receiving applications from persons of under-represented groups, including women, ethnic minorities, disabled veterans, Vietnam-era veterans, and handicapped persons.

970I/K

RESIDENT POSITIONS

Available at all levels in an expanding teaching program in Boston, Massachusetts. Send CV to or contact Ina Gibson, Coordinator, Department of Anesthesiology, St. Elizabeth's Hospital, 736 Cambridge Street, Brighton, MA 02135; (617) 789-2782, FAX (617) 254-6384.

971I

ANESTHESIOLOGISTS—MONTREAL

Board certified/FRCPC. Pediatric academic teaching hospital with all major subspecialties. Guaranteed research time. Interest in pain management and/or cardiovascular anesthesia an advantage. In accordance with Canadian immigration requirements this is directed to Canadian citizens and permanent residents of Canada. McGill University is committed to equity in employment. CV to Dr. D. G. Spence, Director, Montreal Children's Hospital, 2300 Tupper Street, Room C-1118, Montreal, QC, H3H 1P3.

972I

ARKANSAS

Pediatric anesthesia fellowship to begin July 1, 1993. Broad-based training in pediatric anesthesia includes experience in cardiac, pain management, and critical care. Active research program. Prefer applicants who have completed CA-3 level in approved residency program. Must be eligible for Arkansas licensure. Send curriculum vitae to Raeford E. Brown, Jr., MD, Chief, Division of Pediatric Anesthesia, Arkansas Children's Hospital, 800 Marshall Street, Little Rock, AR 72202-3591. An Equal Opportunity Employer.

973I/K

CALIFORNIA

The UCLA Department of Anesthesiology is represented by all anesthesia subspecialties. From time to time faculty positions in the Department become available. Appointment in the CLINICIAN-TEACHER Academic Professorial Series requires clinical and teaching skills, interest or experience in clinical research, eligibility for a California medical license, and ABA certification or in process. Appointment in the REGULAR PROFESSORIAL SERIES (TENURE TRACK) additionally requires evidence of research productivity, scholarly writing, and a commitment to discovery. Appointment as an Associate Professor or Full Professor in either of these academic series requires demonstration that you have been continuously and effectively engaged in creative activity of high quality and significance. Send your inquiry with curriculum vitae and names of five references to Joseph C. Gabel, MD, Department of Anesthesiology, UCLA School of Medicine, Los Angeles, CA 90024-1778. UCLA is an Affirmative Action Equal Opportunity Employer.

974I

PEDIATRIC ANESTHESIOLOGIST

BC/BE fellowship-trained to join private group in southern California. Opportunity exists to head pediatric subsection due to newly established relationship with a local children's hospital. Individual must be proficient and willing to provide care in areas of adult anesthesiology, i.e., OB, trauma, neuro. No cardiac requirements. Call Brian Levine, MD, Mission Anesthesia Medical Associates; (714) 240-6057.

975I

ANESTHESIOLOGIST

AMG, B/C, 8 years' experience. Pediatric fellowship. Current adult experience. Desires F/T same-day surgery or similar. No call. LIC PA, NY, TN, MA. Reply to Box 976I.

976I

DIRECTOR OF OBSTETRIC ANESTHESIOLOGY

The Department of Anesthesiology at the University of Rochester is seeking a Director of Obstetric Anesthesiology, with outstanding qualifications in clinical care, teaching, and research, to assume clinical leadership and to develop advanced education and research programs in obstetric anesthesiology.

Board certification in anesthesiology or its equivalent is required. Academic rank and salary will be commensurate with qualifications. Opportunities for independent or collaborative research are abundant.

Interested candidates should send curriculum vitae to Denham S. Ward, MD, PhD, Professor and Chairman Designate, Department of Anesthesiology, University of Rochester Medical Center, 601 Elmwood Avenue, Rochester, NY 14642. The University of Rochester is an Equal Opportunity Employer.

977IJ

DON'T FAIL THE WRITTEN BOARDS!

Unique study program including memory devices, methods for improved retention, guessing techniques, etc. Practice questions with answers, explanations and references, new Keywords. Get MEDTEXT not imitations. Call 1-800-695-6301 for information 24 hours. Call 1-800-232-TEXT for orders. MC/V accepted.

933H/A

PASS YOUR ORAL BOARDS—FOR ONLY $15.00??!!??

New guide gives you valuable tips, hints, and suggestions for one low price. Send $15.00 check or money order, or write for free further information, to Poterack Systems, Department AA, 4422 Shavano Cross, San Antonio, TX 78230.

935HI

TUTORING FOR WRITTEN AND ORAL BOARD EXAMS

The unique feature of these programs is the maximum class size of four students. Preparation for the written and oral exams are given separately in 3-day blocks in San Francisco and New York. FOR THE WRITTENS, techniques are taught for dealing with the multiple-choice questions. The basic sciences are stressed. FOR THE ORALS, the guided case discussions are stressed. Home study programs are provided. CALL (415) 321-1117.

763I/H

Dial 1-800/RENT-A-DOC

For anesthesiologists and CRNAs. We can provide you with quality locum tenens services to meet your specific coverage needs. Or work locum tenens with us for a change in both your practice and your lifestyle. ReplaceMed * 1-800/736-8236 * PO Box 640 * Michigan City, IN 46360.

832A/L

J. STEPHENS MAYHUGH AND ASSOCIATES, INC. LOCUM TENENS ANESTHESIA SERVICES

Providing top-quality CRNAs to meet your specific needs. Our CRNAs are screened to assure quality in performance as well as personal stability. License verification, curriculum vitae, references procured by us, AANA recertification, malpractice verification are supplied to you. Call 1-800-426-2349 any time.

755I/L

DANIEL & YEAGER LOCUM TENENS

Daniel & Yeager is the only name you need for locum tenens. Anesthesia is our specialty, so you are assured of our personal attention. Earn a premium income while eliminating administrative headaches and malpractice premiums; we cover it all. Call 1-800-264-1919 or write to 200 Clinton Avenue, NW, Suite 400, Huntsville, AL 35801.

Anesthesiology Board Review Courses

August 4-9, 1992 – Chicago

†September 14-19 – Boston

Now, special programs for written and oral boards

OBJECTIVES

- Improve basic and clinical knowledge of anesthesiology
- Assist residents and fellows to better organize for further study
- Prepare candidates to take their written and oral exams

METHODS

- HOME STUDY questions, answers, assignments and keywords
- SEMINAR with projection slides and lecture-note syllabus
- PRACTICE EXAMS for written and oral board exams

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities, but from people who are relatively unknown as well."**

Written Board Review

Lectures and written exam seminars

- Home-study keywords with discussion and questions with answers.
- Six-day lectures with syllabus.
- **Seminars for written exam questions**
- September 14-19.

Oral Board Review

Mock oral exams and lectures

- Home-study, oral-exam stem cases wit pre-op, intra-op and post-op questions.
- Six-day lectures with syllabus and con current mock oral exams most hours.
- **Registration includes one mock oral.**
- Extra public mock oral exam ($80), pr vate mock oral exam ($110).
- August 4-9; September 14-19.

Oral Board Tutorial Days

Choose any days – groups limited to 2

- Home-study, oral-exam stem cases wit pre-op, intra-op and post-op questions.
- Mock oral exams in groups **limited to 24**
- **Includes one public mock oral per da**
- Extra public mock oral exams ($80), pr vate mock oral exams ($110).
- August 4-9; September 14-22.

Two-Part Board Review

Nine mock orals in any two courses

- Any course in 1992, plus any other withi three years. One course may be up to si Oral Board Tutorial days of your choic
- Choose between lectures and concurre mock orals or written exam discussions
- **Nine (9) mock oral exams in grou limited to 24 participants.**

Unconditional Guarantee

- If you fail the next Anesthesiology Boar Exam you take after taking one of thes courses, we will refund half of your las course registration fee and allow you t repeat the course once for FREE.
- This is NOT conditional upon you takin more than one course, or extra mock orals
- Last year, after we first made this guaran tee, **less than 2% requested a refund.**

Alfenta®

(alfentanil HCl) Injection CII

Before prescribing, please consult complete prescribing information, of which the following is a brief summary.

CAUTION: Federal Law Prohibits Dispensing Without Prescription

DESCRIPTION: ALFENTA is a sterile, non-pyrogenic, preservative free aqueous solution containing alfentanil hydrochloride equivalent to 500 µg per ml of alfentanil base for intravenous injection. The solution, which contains sodium chloride for isotonicity, has a pH range of 4.0-6.0.

CONTRAINDICATIONS: ALFENTA (alfentanil hydrochloride) is contraindicated in patients with known hypersensitivity to the drug.

WARNINGS: ALFENTA SHOULD BE ADMINISTERED ONLY BY PERSONS SPECIFICALLY TRAINED IN THE USE OF INTRAVENOUS AND GENERAL ANESTHETIC AGENTS AND IN THE MANAGEMENT OF RESPIRATORY EFFECTS OF POTENT OPIOIDS. AN OPIOID ANTAGONIST, RESUSCITATIVE AND INTUBATION EQUIPMENT AND OXYGEN SHOULD BE READILY AVAILABLE. BECAUSE OF THE POSSIBILITY OF DELAYED RESPIRATORY DEPRESSION, MONITORING OF THE PATIENT MUST CONTINUE WELL AFTER SURGERY. ALFENTA (alfentanil hydrochloride) administered in initial dosages up to 20 µg/kg may cause skeletal muscle rigidity, particularly of the truncal muscles. The incidence and severity of muscle rigidity is usually dose-related. Administration of ALFENTA at anesthetic induction dosages (above 130 µg/kg) will consistently produce muscular rigidity with an immediate onset. The onset of muscular rigidity occurs earlier than with other opioids. ALFENTA may produce muscular rigidity that involves all skeletal muscles, including those of the neck and extremities. The incidence may be reduced by: 1) routine methods of administration of neuromuscular blocking agents for balanced opioid anesthesia; 2) administration of up to ¼ of the full paralyzing dose of a neuromuscular blocking agent just prior to administration of ALFENTA at dosages up to 130 µg/kg; following loss of consciousness, a full paralyzing dose of a neuromuscular blocking agent should be administered; or 3) simultaneous administration of ALFENTA and a full paralyzing dose of a neuromuscular blocking agent when ALFENTA is used in rapidly administered anesthetic dosages (above 130 µg/kg). The neuromuscular blocking agent used should be appropriate for the patient's cardiovascular status. Adequate facilities should be available for postoperative monitoring and ventilation of patients administered ALFENTA. It is essential that these facilities be fully equipped to handle all degrees of respiratory depression.

PRECAUTIONS: DELAYED RESPIRATORY DEPRESSION, RESPIRATORY ARREST, BRADYCARDIA, ASYSTOLE, ARRHYTHMIAS AND HYPOTENSION HAVE ALSO BEEN REPORTED. THEREFORE, VITAL SIGNS MUST BE MONITORED CONTINUOUSLY.

General: The initial dose of ALFENTA (alfentanil hydrochloride) should be appropriately reduced in elderly and debilitated patients. The effect of the initial dose should be considered in determining supplemental doses. In obese patients (more than 20% above ideal total body weight), the dosage of ALFENTA should be determined on the basis of lean body weight. In one clinical trial, the dose of ALFENTA required to produce anesthesia, as determined by appearance of delta waves in EEG, was 40% lower in geriatric patients than that needed in healthy young patients. In patients with compromised liver function and in geriatric patients, the plasma clearance of ALFENTA may be reduced and postoperative recovery may be prolonged. Induction doses of ALFENTA should be administered slowly (over three minutes). Administration may produce loss of vascular tone and hypotension. Consideration should be given to fluid replacement prior to induction. Diazepam administered immediately prior to or in conjunction with high doses of ALFENTA may produce vasodilation, hypotension and result in delayed recovery. Bradycardia produced by ALFENTA may be treated with atropine. Severe bradycardia and asystole have been successfully treated with atropine and conventional resuscitative methods. The hemodynamic effects of a particular muscle relaxant and the degree of skeletal muscle relaxation required should be considered in the selection of a neuromuscular blocking agent. Following an anesthetic induction dose of ALFENTA, requirements for volatile inhalation anesthetics or ALFENTA infusion are reduced by 30 to 50% for the first hour of maintenance. Administration of ALFENTA infusion should be discontinued at leas 10-15 minutes prior to the end of surgery. Respiratory depression caused by opioid analgesics can be reversed by opioid antagonists such as naloxone. Because the duration of respiratory depression produced by ALFENTA may last longer than the duration of the opioid antagonist action, appropriate surveillance should be maintained. As with all potent opioids, profound analgesia is accompanied by respiratory depression and diminished sensitivity to CO_2 stimulation which may persist into or recur in the postoperative period. Intraoperative hyperventilation may further alter postoperative response to CO_2. Appropriate postoperative monitoring should be employed, particularly after infusions and large doses of ALFENTA, to ensure that adequate spontaneous breathing is established and maintained in the absence of stimulation prior to discharging the patient from the recovery area.

Head Injuries: ALFENTA may obscure the clinical course of patients with head injuries.

Impaired Respiration: ALFENTA should be used with caution in patients with pulmonary disease, decreased respiratory reserve or potentially compromised respiration. In such patients, opioids may additionally decrease respiratory drive and increase airway resistance. During anesthesia, this can be managed by assisted or controlled respiration.

Impaired Hepatic or Renal Function: In patients with liver or kidney dysfunction, ALFENTA should be administered with caution due to the importance of these organs in the metabolism and excretion of ALFENTA.

Drug Interactions: Both the magnitude and duration of central nervous system and cardiovascular effects may be enhanced when ALFENTA is administered in combination with other CNS depressants such as barbiturates, tranquilizers, opioids, or inhalation general anesthetics. Postoperative respiratory depression may be enhanced or prolonged by these agents. In such cases of combined treatment, the dose of one or both agents should be reduced. Limited clinical experience indicates that requirements for volatile inhalation anesthetics are reduced by 30 to 50% for the first sixty (60) minutes following ALFENTA induction. The concomitant use of erythromycin with ALFENTA can significantly inhibit ALFENTA clearance and may increase the risk of prolonged or delayed respiratory depression. Perioperative administration of drugs affecting hepatic blood flow or enzyme function may reduce plasma clearance and prolong recovery.

Carcinogenesis, Mutagenesis and Impairment of Fertility: No long-term animal studies of ALFENTA have been performed to evaluate carcinogenic potential. The micronucleus test in female rats and the dominant lethal test in female and male mice revealed that single intravenous doses of ALFENTA as high as 20 mg/kg (approximately 40 times the upper human dose) produced no structural chromosome mutations or induction of dominant lethal mutations. The Ames *Salmonella typhimurium* metabolic activating test also revealed no mutagenic activity.

Pregnancy Category C: ALFENTA has been shown to have an embryocidal effect in rats and rabbits when given in doses 2.5 times the upper human dose for a period of 10 days to over 30 days. These effects could have been due to maternal toxicity (decreased food consumption with increased mortality) following prolonged administration of the drug. No evidence of teratogenic effects has been observed after administration of ALFENTA in rats or rabbits. There are no adequate and well-controlled studies in pregnant women. ALFENTA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Labor and Delivery: There are insufficient data to support the use of ALFENTA in labor and delivery. Placental transfer of the drug has been reported; therefore, use in labor and delivery is not recommended.

Nursing Mothers: In one study of nine women undergoing post-partum tubal ligation, significant levels of ALFENTA were detected in colostrum four hours after administration of 60 µg/kg of ALFENTA, with no detectable levels present after 28 hours. Caution should be exercised when ALFENTA is administered to a nursing woman.

Pediatric Use: Adequate data to support the use of ALFENTA in children under 12 years of age are not presently available.

ADVERSE REACTIONS: The most common adverse reactions, respiratory depression and skeletal muscle rigidity, are extensions of known pharmacological effects of opioids. See CLINICAL PHARMACOLOGY, WARNINGS and PRECAUTIONS on the management of respiratory depression and skeletal muscle rigidity. Delayed respiratory depression, respiratory arrest, bradycardia, asystole, arrhythmias and hypotension have also been reported. The reported incidences of adverse reactions listed in the following table are derived from controlled and open clinical trials involving 1183 patients, of whom 785 received ALFENTA. The controlled trials involved treatment comparisons with fentanyl, thiopental sodium, enflurane, saline placebo and halothane. Incidences are based on disturbing and nondisturbing adverse reactions reported. The comparative incidence of certain side effects is influenced by the type of use, e.g., chest wall rigidity has a higher reported incidence in clinical trials of alfentanil induction, and by the type of surgery, e.g., nausea and vomiting have a higher incidence in patients undergoing gynecologic surgery.

Percent	ALFENTA (N = 785)	Fentanyl (N = 243)	Thiopental Sodium (N = 66)	Enflurane (N = 55)	Halothane (N = 18)	Saline Placebo* (N = 18)
Gastrointestinal						
Nausea	28	44	14	5	0	22
Vomiting	18	31	11	9	13	17
Cardiovascular						
Bradycardia	14	7	8	0	0	0
Tachycardia	12	12	39	36	31	11
Hypotension	10	8	7	7	0	0
Hypertension	18	13	30	20	6	0
Arrhythmia	2	2	5	4	6	0
Musculoskeletal						
Chest Wall Rigidity	17	12	0	0	0	0
Skeletal Muscle Movements	6	2	6	2	0	0
Respiratory						
Apnea	7	0	0	0	0	0
Postoperative Respiratory Depression	2	2	0	0	0	0
CNS						
Dizziness	3	5	0	0	0	0
Sleepiness/ Postoperative Sedation	2	8	2	0	0	6
Blurred Vision	2	2	0	0	0	0

*From two clinical trials, one involving supplemented balanced barbiturate / nitrous oxide anesthesia and one in healthy volunteers who did not undergo surgery.

In addition, other adverse reactions less frequently reported (1% or less) were: Laryngospasm, bronchospasm, postoperative confusion, headache, shivering, postoperative euphoria, hypercarbia, pain on injection, urticaria, and itching. Some degree of skeletal muscle rigidity should be expected with induction doses of ALFENTA.

DRUG ABUSE AND DEPENDENCE: ALFENTA (alfentanil hydrochloride) is a Schedule II controlled drug substance that can produce drug dependence of the morphine type and therefore has the potential for being abused.

OVERDOSAGE: Overdosage would be manifested by extension of the pharmacological actions of ALFENTA (alfentanil hydrochloride) (see CLINICAL PHARMACOLOGY) as with other potent opioid analgesics. No experience of overdosage with ALFENTA was reported during clinical trials. The intravenous LD_{50} of ALFENTA is 43.0-50.9 mg/kg in rats, 72.2-73.6 mg/kg in mice, 71.8-81.9 mg/kg in guinea pigs and 59.5-87.5 mg/kg in dogs. Intravenous administration of an opioid antagonist such as naloxone should be employed as a specific antidote to manage respiratory depression. The duration of respiratory depression following overdosage with ALFENTA may be longer than the duration of action of the opioid antagonist. Administration of an opioid antagonist should not preclude immediate establishment of a patent airway, administration of oxygen, and assisted or controlled ventilation as indicated for hypoventilation or apnea. If respiratory depression is associated with muscular rigidity, a neuromuscular blocking agent may be required to facilitate assisted or controlled ventilation. Intravenous fluids and vasoactive agents may be required to manage hemodynamic instability.

DOSAGE AND ADMINISTRATION: The dosage of ALFENTA (alfentanil hydrochloride) should be individualized in each patient according to body weight, physical status, underlying pathological condition, use of other drugs, and type and duration of surgical procedure and anesthesia. In obese patients (more than 20% above ideal total body weight), the dosage of ALFENTA should be determined on the basis of lean body weight. The dose of ALFENTA should be reduced in elderly or debilitated patients (see PRECAUTIONS). Vital signs should be monitored routinely. Protect from light. Store at room temperature 15°-30° C (59°-86° F).

A LOGICAL CHOICE

CRUCIAL PARAMETERS IN SELECTING A NEUROMUSCULAR BLOCKING AGENT

	Norcuron® (vecuronium bromide) for injection	Atracurium besylate
HEMODYNAMICS	No significant variations in blood pressure, cardiac output, or systemic vascular resistance.[1]	Statistically significant variations in blood pressure, cardiac output, and systemic vascular resistance.[1] ($P<.05$)
HISTAMINE	Available clinical experience indicates that reactions commonly associated with histamine release are unlikely to occur.[1-4]	Precautions advised for patients in whom substantial histamine release would be hazardous (eg, clinically significant cardiovascular disease, asthma).[5]
RECOVERY		
To 25% of control	25-40 min[3]	35-45 min[5]
To 95% of control	45-65 min[3]	60-70 min[5]
DOSING FLEXIBILITY	The initial recommended dose is 0.08-0.1 mg/kg. Dose can be increased up to 0.28 mg/kg for long cases without significant histamine release or related cardiovascular side effects.[1,3,4]	Initial recommended dose is 0.4-0.5 mg/kg. A moderate histamine release and significant falls in blood pressure have been seen following a dose of 0.5 mg/kg ($P<.05$) and 0.6 mg/kg.[*2,5,6]
STORAGE & SHELF LIFE	2-year shelf life in lyophilized form at room temperature.[†] Can be reconstituted with various IV solutions including Lactated Ringers.[‡]	2-year shelf life under constant refrigeration.[†] Upon removal from refrigeration to room temperature storage, use within 14 days even if rerefrigerated.[5]

[*] Dose of atracurium above 0.5 mg/kg is not recommended.
[†] As originally supplied by the respective manufacturers.
[‡] Storage after reconstitution varies with solution. See package insert.

Norcuron®

(vecuronium bromide) for injection

A LOGICAL CHOICE FOR NEUROMUSCULAR BLOCKADE

See following page for brief summary of prescribing information.

Organon
ORGANON INC.
WEST ORANGE
NEW JERSEY 07052

Norcuron®
(vecuronium bromide) for injection

Before prescribing, please consult complete product information, a summary of which follows:

THIS DRUG SHOULD BE ADMINISTERED BY ADEQUATELY TRAINED INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS, AND HAZARDS.

CONTRAINDICATIONS: Norcuron® is contraindicated in patients known to have a hypersensitivity to it.

WARNINGS: NORCURON® SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH ITS ACTIONS AND THE POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND REVERSAL AGENTS ARE IMMEDIATELY AVAILABLE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR CONTROL RESPIRATION. TO REDUCE THE POSSIBILITY OF PROLONGED NEUROMUSCULAR BLOCKADE AND OTHER POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING LONG-TERM USE IN THE ICU, NORCURON® OR ANY OTHER NEUROMUSCULAR BLOCKING AGENT SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSES BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH ITS ACTIONS AND WHO ARE FAMILIAR WITH APPROPRIATE PERIPHERAL NERVE STIMULATOR MUSCLE MONITORING TECHNIQUES (see PRECAUTIONS). In patients who are known to have myasthenia gravis or the myasthenic (Eaton-Lambert) syndrome, small doses of Norcuron® may have profound effects. In such patients, a peripheral nerve stimulator and use of a small test dose may be of value in monitoring the response to administration of muscle relaxants.

PRECAUTIONS:

Renal Failure: Norcuron® is well tolerated without clinically significant prolongation of neuromuscular blocking effect in patients with renal failure who have been optimally prepared for surgery by dialysis. Under emergency conditions in anephric patients some prolongation of neuromuscular blockage may occur; therefore, if anephric patients cannot be prepared for non-elective surgery, a lower initial dose of Norcuron® should be considered.

Altered Circulation Time: Conditions associated with slower circulation time in cardiovascular disease, old age, edematous states resulting in increased volume of distribution may contribute to a delay in onset time, therefore dosage should not be increased.

Hepatic Disease: Limited experience in patients with cirrhosis or cholestasis has revealed prolonged recovery time in keeping with the role the liver plays in Norcuron® metabolism and excretion. Data currently available do not permit dosage recommendations in patients with impaired liver function.

Long-term Use in I.C.U.: In the intensive care unit, in rare cases, long-term use of neuromuscular blocking drugs to facilitate mechanical ventilation may be associated with prolonged paralysis and/or skeletal muscle weakness that may be first noted during attempts to wean such patients from the ventilator. Typically, such patients receive other drugs such as broad spectrum antibiotics, narcotics and/or steroids and may have electrolyte imbalance and diseases which lead to electrolyte imbalance, hypoxic episodes of varying duration, acid-base imbalance and extreme debilitation, any of which may enhance the actions of a neuromuscular blocking agent. Additionally, patients immobilized for extended periods frequently develop symptoms consistent with disuse muscle atrophy. The recovery picture may vary from regaining movement and strength in all muscles to initial recovery of movement of the facial and small muscles of the extremities then to the remaining muscles. In rare cases recovery may be over an extended period of time and may even, on occasion, involve rehabilitation. Therefore, when there is a need for long-term mechanical ventilation, the benefits-to-risk ratio of neuromuscular blockade must be considered. Continuous infusion or intermittent bolus dosing to support mechanical ventilation has not been studied sufficiently to support dosage recommendations.

IN THE INTENSIVE CARE UNIT, APPROPRIATE MONITORING, WITH THE USE OF A PERIPHERAL NERVE STIMULATOR TO ASSESS THE DEGREE OF NEUROMUSCULAR BLOCKADE, IS RECOMMENDED TO HELP PRECLUDE POSSIBLE PROLONGATION OF THE BLOCKADE. WHENEVER THE USE OF NORCURON® OR ANY NEUROMUSCULAR BLOCKING AGENT IS CONTEMPLATED IN THE ICU, IT IS RECOMMENDED THAT NEUROMUSCULAR TRANSMISSION BE MONITORED CONTINUOUSLY DURING ADMINISTRATION AND RECOVERY WITH THE HELP OF A NERVE STIMULATOR. ADDITIONAL DOSES OF NORCURON® OR ANY OTHER NEUROMUSCULAR BLOCKING AGENT SHOULD NOT BE GIVEN BEFORE THERE IS A DEFINITE RESPONSE TO T$_1$ OR TO THE FIRST TWITCH. IF NO RESPONSE IS ELICITED, INFUSION ADMINISTRATION SHOULD BE DISCONTINUED UNTIL A RESPONSE RETURNS.

Severe Obesity or Neuromuscular Disease: Patients with severe obesity or neuromuscular disease may pose airway and/or ventilatory problems requiring special care before, during and after the use of neuromuscular blocking agents such as Norcuron®.

Malignant Hyperthermia: Many drugs used in anesthetic practice are suspected of being capable of triggering a potentially fatal hypermetabolism of skeletal muscle known as malignant hyperthermia. There are insufficient data derived from screening in susceptible animals (swine) to establish whether or not Norcuron® is capable of triggering malignant hyperthermia.

C.N.S.: Norcuron® has no known effect on consciousness, the pain threshold or cerebration. Administration must be accompanied by adequate anesthesia or sedation.

Drug Interactions: Prior administration of succinylcholine may enhance the neuromuscular blocking effect of Norcuron® (vecuronium bromide) for injection and its duration of action. If succinylcholine is used before Norcuron®, the administration of Norcuron® should be delayed until the succinylcholine effect shows signs of wearing off. With succinylcholine as the intubating agent, initial doses of 0.04-0.06 mg/kg of Norcuron® may be administered to produce complete neuromuscular block with clinical duration of action of 25-30 minutes. The use of Norcuron® before succinylcholine, in order to attenuate some of the side effects of succinylcholine, has not been sufficiently studied.

Other nondepolarizing neuromuscular blocking agents (pancuronium, d-tubocurarine, metocurine, and gallamine) act in the same fashion as does Norcuron®, therefore these drugs and Norcuron® may manifest an additive effect when used together. There are insufficient data to support concomitant use of Norcuron® and other competitive muscle relaxants in the same patient.

Inhalational Anesthetics: Use of volatile inhalational anesthetics such as enflurane, isoflurane, and halothane with Norcuron® will enhance neuromuscular blockade. Potentiation is most prominent with use of enflurane and isoflurane. With the above agents the initial dose of Norcuron® may be the same as with balanced anesthesia unless the inhalational anesthetic has been administered for a sufficient time at a sufficient dose to have reached clinical equilibrium.

Antibiotics: Parenteral/intraperitoneal administration of high doses of certain antibiotics may intensify or produce neuromuscular block on their own. The following antibiotics have been associated with various degrees of paralysis: aminoglycosides (such as neomycin, streptomycin, kanamycin, gentamicin, and dihydrostreptomycin); tetracyclines; bacitracin; polymyxin B; colistin; and sodium colistimethate. If these or other newly introduced antibiotics are used in conjunction with Norcuron®, unexpected prolongation of neuromuscular block should be considered a possibility.

Other: Experience concerning injection of quinidine during recovery from use of other muscle relaxants suggest that recurrent paralysis may occur. This possibility must also be considered for Norcuron®. Norcuron® induced neuromuscular blockade has been counteracted by alkalosis and enhanced by acidosis in experimental animals (cat). Electrolyte imbalance and diseases which lead to electrolyte imbalance, such as adrenal cortical insufficiency, have been shown to alter neuromuscular blockade. Depending on the nature of the imbalance, either enhancement or inhibition may be expected. Magnesium salts, administered for the management of toxemia of pregnancy, may enhance the neuromuscular blockade.

Drug/laboratory test interactions: None known.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential or impairment of fertility.

Pregnancy: Pregnancy Category C: Animal reproduction studies have not been conducted with Norcuron®. It is also not known whether Norcuron® can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Norcuron® should be given to a pregnant woman only if clearly needed.

Pediatric Use: Infants under 1 year of age but older than 7 weeks, also tested under halothane anesthesia, are moderately more sensitive to Norcuron® on a mg/kg basis than adults and take about 1½ times as long to recover. Information presently available does not permit recommendations for usage in neonates.

ADVERSE REACTIONS: The most frequent adverse reaction to nondepolarizing blocking agents as a class consists of an extension of the drug's pharmacological action beyond the time period needed. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle paralysis resulting in respiration insufficiency or apnea.

Inadequate reversal of the neuromuscular blockade is possible with Norcuron® as with all curariform drugs. These adverse reactions are managed by manual or mechanical ventilation until recovery is judged adequate. Little or no increase in intensity of blockade or duration of action of Norcuron® is noted from the use of thiobarbiturates, narcotic analgesics, nitrous oxide, or droperidol. See OVERDOSAGE for discussion of other drugs used in anesthetic practice which also cause respiratory depression.

Prolonged to profound extensions of paralysis and/or muscle weakness as well as muscle atrophy have been reported after long-term use to support mechanical ventilation in the intensive care unit (see PRECAUTIONS).

The administration of Norcuron® has been associated with rare instances of hypersensitivity reactions (bronchospasm, hypotension and/or tachycardia, sometimes associated with acute urticaria or erythema).

OVERDOSAGE: The possibility of iatrogenic overdosage can be minimized by carefully monitoring muscle twitch response to peripheral nerve stimulation.

Excessive doses of Norcuron® produce enhanced pharmacological effects. Residual neuromuscular blockage beyond the time period needed may occur with Norcuron® as with other neuromuscular blockers. This may be manifested by skeletal muscle weakness, decreased respiratory reserve, low tidal volume, or apnea. A peripheral nerve stimulator may be used to assess the degree of residual neuromuscular blockade from other causes of decreased respiratory reserve.

Respiratory depression may be due either wholly or in part to other drugs used during the conduct of general anesthesia such as narcotics, thiobarbiturates and other central nervous system depressants. Under such circumstances, the primary treatment is maintenance of a patent airway and manual or mechanical ventilation until complete recovery of normal respiration is assured. Regonol® (pyridostigmine bromide) injection, neostigmine, or edrophonium, in conjunction with atropine or glycopyrrolate will usually antagonize the skeletal muscle relaxant action of Norcuron®. Satisfactory reversal can be judged by adequacy of skeletal muscle tone and by adequacy of respiration. A peripheral nerve stimulator may also be used to monitor restoration of twitch height. Failure of prompt reversal (within 30 minutes) may occur in the presence of extreme debilitation, carcinomatosis, and with concomitant use of certain broad spectrum antibiotics, or anesthetic agents and other drugs which enhance neuromuscular blockade or cause respiratory depression of their own. Under such circumstances the management is the same as that of prolonged neuromuscular blockade. Ventilation must be supported by artificial means until the patient has resumed control

DOSAGE AND ADMINISTRATION: Before prescribing, please consult complete product information. Norcuron® (vec uronium bromide) for injection is for intravenous use only. This drug should be administered by or under the supervision experienced clinicians familiar with the use of neuromuscular blocking agents. Dosage must be individualized in each ca dosage information which follows is derived from studies based upon units of drug per unit of body weight and is intend serve as a guide only, especially regarding enhancement of neuromuscular blockade of Norcuron® by volatile anesthetic by prior use of succinylcholine (see PRECAUTIONS/Drug Interactions). Parenteral drug products should be inspected vi for particulate matter and discoloration prior to administration whenever solution and container permit.

To obtain maximum clinical benefits of Norcuron® and to minimize the possibility of overdosage, the monitoring of m twitch response to peripheral nerve stimulation is advised.

The recommended initial dose of Norcuron® is 0.08 to 0.10 mg/kg (1.4 to 1.75 times the ED$_{90}$) given as an intravenou injection. This dose can be expected to produce good or excellent non-emergency intubation conditions in 2.5 to 3 minu after injection. Under balanced anesthesia, clinically required neuromuscular blockade lasts approximately 25-30 minute recovery to 25% of control achieved approximately 25 to 40 minutes after injection and recovery to 95% of control achie approximately 45-65 minutes after injection. In the presence of potent inhalation anesthetics, the neuromuscular blockin of Norcuron® is enhanced. If Norcuron® is first administered more than 5 minutes after the start of inhalation agent or w steady state has been achieved, the initial Norcuron® dose may be reduced by approximately 15%, i.e., 0.060 to 0.085 n

Prior administration of succinylcholine may enhance the neuromuscular blocking effect and duration of action of Norc If intubation is performed using succinylcholine, a reduction of initial dose of Norcuron® to 0.04-0.06 mg/kg with inhala anesthesia and 0.05-0.06 mg/kg with balanced anesthesia may be required.

During prolonged surgical procedures, maintenance doses of 0.010 to 0.015 mg/kg of Norcuron® are recommended; a initial Norcuron® injection, the first maintenance dose will generally be required within 25 to 40 minutes. However, clinic ria should be used to determine the need for maintenance doses. Since Norcuron® lacks clinically important cumulative subsequent maintenance doses, if required, may be administered at relatively regular intervals for each patient, ranging a imately from 12 to 15 minutes under balanced anesthesia, slightly longer under inhalation agents. (If less frequent admin tion is desired, higher maintenance doses may be administered.)

Should there be reason for the selection of larger doses in individual patients, initial doses ranging from 0.15 mg/kg u 0.28 mg/kg have been administered during surgery under halothane anesthesia without ill effects to the cardiovascular s being noted as long as ventilation is properly maintained.

Use by Continuous Infusion: After an intubating dose of 80-100 µg/kg, a continuous infusion of 1 µg/kg/min can b ated approximately 20-40 min later. Infusion of Norcuron® should be initiated only after early evidence of spontaneous r from the bolus dose. Long-term intravenous infusion to support mechanical ventilation in the intensive care unit has not studied sufficiently to support dosage recommendations (see PRECAUTIONS).

The infusion of Norcuron® should be individualized for each patient. The rate of administration should be adjusted ac to the patient's twitch response as determined by peripheral nerve stimulation. An initial rate of 1 µg/kg/min is recomme with the rate of the infusion adjusted thereafter to maintain a 90% suppression of twitch response. Average infusion rates range from 0.8 to 1.2 µg/kg/min.

Inhalation anesthetics, particularly enflurane and isoflurane may enhance the neuromuscular blocking action of non-depolarizing muscle relaxants. In the presence of steady-state concentrations of enflurane or isoflurane, it may be necess reduce the rate of infusion 25-60 percent, 45-60 min after the intubating dose. Under halothane anesthesia it may not be essary to reduce the rate of infusion.

Spontaneous recovery and reversal of neuromuscular blockade following discontinuation of Norcuron® infusion may expected to proceed at rates comparable to that following a single bolus dose.

Infusion solutions of Norcuron® can be prepared by mixing Norcuron® with an appropriate infusion solution such as glucose in water, 0.9% NaCl, 5% glucose in saline, or Lactated Ringers. Unused portions of infusion solutions should b discarded.

Infusion rates of Norcuron® can be individualized for each patient using the following table:

Drug Delivery Rate (µg/kg/min)	Infusion Delivery Rate (mL/kg/min)	
	0.1 mg/mL*	0.2 mg/mL†
0.7	0.007	0.0035
0.8	0.008	0.0040
0.9	0.009	0.0045
1.0	0.010	0.0050
1.1	0.011	0.0055
1.2	0.012	0.0060
1.3	0.013	0.0065

*10 mg of Norcuron® in 100 mL solution †20 mg of Norcuron® in 100 mL solution

The following table is a guideline for mL/min delivery for a solution of 0.1 mg/mL (10 mg in 100 mL) with an infusion pu

NORCURON® INFUSION RATE – mL/MIN

Amount of Drug µg/kg/min	Patient Weight – kg						
	40	50	60	70	80	90	1
0.7	0.28	0.35	0.42	0.49	0.56	0.63	0.
0.8	0.32	0.40	0.48	0.56	0.64	0.72	0.
0.9	0.36	0.45	0.54	0.63	0.72	0.81	0.
1.0	0.40	0.50	0.60	0.70	0.80	0.90	1.
1.1	0.44	0.55	0.66	0.77	0.88	0.99	1.
1.2	0.48	0.60	0.72	0.84	0.96	1.08	1.
1.3	0.52	0.65	0.78	0.91	1.04	1.17	1.

NOTE: If a concentration of 0.2 mg/mL is used (20 mg in 100 mL), the rate should be decreased by one-half.

Dosage in Children: Older children (10 to 17 years of age) have approximately the same dosage requirements (mg/kg adults and may be managed the same way. Younger children (1 to 10 years of age) may require a slightly higher initial do may also require supplementation slightly more often than adults. Infants under one year of age but older than 7 weeks a moderately more sensitive to Norcuron® on a mg/kg basis than adults and take about 1½ times as long to recover. See a subsection of PRECAUTIONS titled Pediatric Use. Information presently available does not permit recommendation on us neonates (see PRECAUTIONS). There are insufficient data concerning continuous infusion of vecuronium in children, the no dosing recommendation can be made.

COMPATIBILITY: Norcuron® is compatible in solution with:

0.9% NaCl solution   Sterile water for injection   Lactated Ringers
5% glucose in water   5% glucose in saline

Use within 24 hours of mixing with the above solutions.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration ever solution and container permit.

HOW SUPPLIED:

10 mL vials (10 mg vecuronium bromide) and 10 mL prefilled syringes of diluent (bacteriostatic water for injection, USP). 22 g 1¼" needle.   Boxes of 10   NDC No. 0052-0441-60
10 mL vials (10 mg vecuronium bromide) and 10 mL vials of diluent (bacteriostatic water for injection, USP)
Boxes of 10   NDC No. 0052-0441-17
10 mL vials (10 mg vecuronium bromide) only; DILUENT NOT SUPPLIED.   Boxes of 10   NDC No. 0052-0441-1
20 mL vials (20 mg vecuronium bromide) only; DILUENT NOT SUPPLIED.   Boxes of 10   NDC No. 0052-0442-

STORAGE: 15°-30°C (59°-86°F). Protect from light.

AFTER RECONSTITUTION:

- When reconstituted with supplied bacteriostatic water for injection: CONTAINS BENZYL ALCHOHOL, WHICH IS NOT INTENDED FOR USE IN NEWBORNS. Use within 5 days. May be stored at room temperature or refrigerated.
- When reconstituted with sterile water for injection or other compatible I.V. solutions. Refrigerate vial. Use within 24 ho Single use only. Discard unused portion.

Caution: Federal law prohibits dispensing without prescription.

IARS 67th CONGRESS

MARCH 19 -23, 1993

San Diego Marriott
Hotel & Marina

INTERNATIONAL ANESTHESIA RESEARCH SOCIETY

TUTORIALS

The Program Committee is pleased to announce an extensive Tutorial Program which features small schoolroom sessions that offer opportunities for informal discussions with the experts.

The 67th Congress topics include: Ambulatory Anesthesia; Deep Hypothermic Circulatory Arrest; Fiberoptic Bronchoscopy; Resident Education; Hemodynamic Misadventures; Running a Pain Service; Practice Opportunities; Regional Blocks; Statistics; TEE for the Neophyte; TEE Advanced Applications.

Detailed program information will be sent to all IARS members in December, 1992.

Anesthesia & Analgesia (ISSN 0003-2999) is issued monthly for the IARS in two indexed volumes per year by Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010. Printed in USA. © 1992 by the International Anesthesia Research Society. Second class postage paid at New York, NY and at additional mailing offices. Subscription information for 1992 applying to IARS members: USA and possessions, $95.00 per year; in all other countries, $120.00. (See General Information in this issue for further details regarding membership.) Subscription information for 1992 applying to non-IARS members: Institutions, $150.00; nonmember individuals, $110.00. Outside the USA and possessions, please add $35.00 for surface postage and handling. For airmail, add $80.00 in USA, Canada, and Mexico; $70.00 for surface airlift to Europe; $85.00 for surface airlift to Japan; and $160.00 for airmail to the rest of the world. Postmaster: Send address changes to: Anesthesia & Analgesia, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

A Bair by any other name…

just isn't the same. Wouldn't you rather have the tested, the proven, the published, the original — "the Bair Hugger?" Bair Hugger Therapy revolutionized patient warming five years ago. Now, a number of imitators are introducing convective warming products.

Consider the differences. Only Bair Hugger Warming's unique design *hugs*, surrounding the patient with warm air for maximum heat transfer. Bair Hugger Blankets are made of recycled tissue, soft against your patient's skin and environmentally responsible. Only Bair Hugger Therapy has been *proven* effective in numerous independent studies. And only Bair Hugger Warming can claim over three million safe and effective patient therapies. Don't your patients deserve a hug today? Bair Hugger® Warming Therapy. From Augustine Medical, Inc.

Please visit us at booth #'s 638–641 at the ASA trade show — Oct. 19th – 21st in New Orleans.

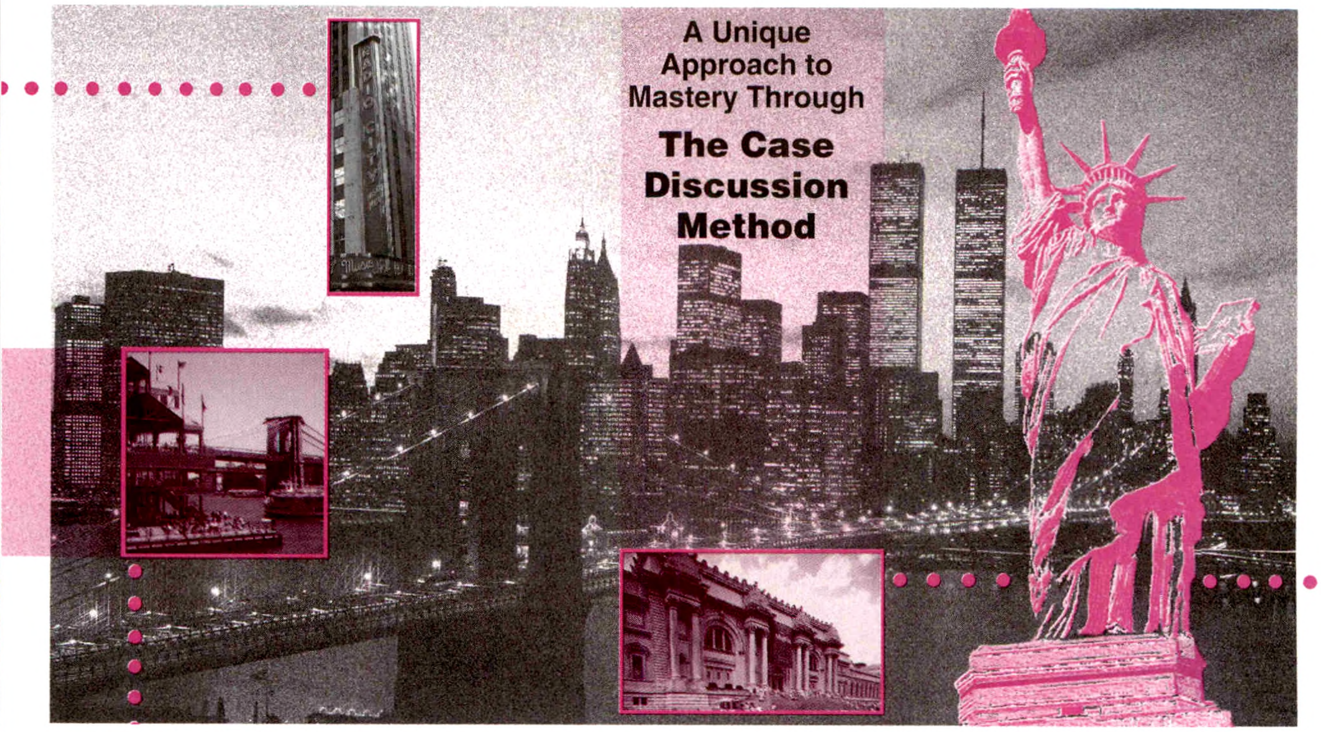
ANESTHESIOLOGY

COMPREHENSIVE REVIEW XIII



SUN.-FRI., MARCH 28-APRIL 2, 1993 **WALDORF=ASTORIA HOTEL, NY**

This popular, intensive, six day course provides an in-depth review of the current practice of Anesthesiology with emphasis on recent advances. The methods utilized in examining up-to-date clinical practice alternatives are particularly valuable in preparing for clinical competence evaluation.

The **format** emphasizes interactive case discussions on a daily basis and an opportunity for each registrant to discuss practice dilemmas in small groups.

Because of the **new emphasis** on interactive discussions, registration will be limited to a first-come first-serve basis.

ANESTHESIA & ANALGESIA

Journal of the International Anesthesia Research Society

The **International Anesthesia Research Society** is a nonprofit, scientific, and educational corporation in the state of Ohio. Members of the Board of Trustees of the Society are: David R. Bevan, MA, MB, BChir, Michael K. Cahalan, MD, Douglas B. Craig, MD, FRCPC, Bruce F. Cullen, MD, Noel W. Lawson, MD, Edward D. Miller, Jr, MD, Dean H. Morrow, MD, Joseph G. Reves, MD, Robert K. Stoelting, MD, Stephen J. Thomas, MD, John L. Waller, MD, and K. C. Wong, MD, PhD. Emeritus Trustees are: E. Paul Didier, MD, Paul R. Dumke, MD, John T. Martin, MD, Emerson A. Moffitt, MD, Morris J. Nicholson, MD, and B. B. Sankey, MD.

Anesthesia & Analgesia (ISSN 0003-2999) is issued monthly for the IARS in two indexed volumes per year by Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010. Printed in USA. © 1992 by the International Anesthesia Research Society. Second class postage paid at New York, NY and at additional mailing offices.

Subscription information for 1992 applying to IARS members: USA and possessions, $95.00 per year; in all other countries, $120.00. Membership is available to individuals with doctorate degrees in medicine, osteopathy, dentistry, veterinary medicine, or other disciplines who are engaged in active clinical practice of or research in anesthesiology. Associate Membership is available to individuals certified, licensed, or accredited by anesthesia-related professions (CRNA, CRTT, RRT, Physician Assistant). Educational Membership (at a reduced price) is available to interns, residents, and students in nurse anesthesia and related training programs, for a 2-, 3-, or 4-year period upon completion of application including certification by applicant's program director.

All membership payments and correspondence regarding IARS member subscriptions should be sent to: International Anesthesia Research Society, Suite 140, 2 Summit Park Drive, Cleveland, OH 44131-2553.

Subscription information for 1992 applying to non-IARS members: Institutions, $150.00; nonmember individuals, $110.00. Outside the USA and possessions, please add $35.00 for surface postage and handling. For airmail, add $80.00 in USA, Canada, and Mexico; $70.00 for surface airlift to Europe; $85.00 for surface airlift to Japan; and $160.00 for airmail to the rest of the world. Postmaster: Send address changes to: *Anesthesia & Analgesia*, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

Orders and inquiries regarding institutional and nonmember individual subscriptions should be directed to: Journals Fulfillment, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

Single issues: Single copy information is available from Elsevier Science Publishing Co., Inc., upon request. Back volume (all issues prior to 1983) information is available from the IARS.

Advertising inquiries should be addressed to: Pharmaceutical Media, Inc., 440 Park Avenue South, 14th Floor, New York, NY 10016. This journal is printed on acid-free paper.

CHAIRPERSON, DEPARTMENT OF ANESTHESIOLOGY

Allegheny General Hospital, the Allegheny Campus of the Medical College of Pennsylvania, is seeking qualified candidates for the position of Chairperson of the Department of Anesthesiology. Allegheny General Hospital is a 746-bed regional referral medical center and teaching hospital located in Pittsburgh, Pennsylvania, with 13 independent residency and 7 fellowship programs. Allegheny offers a full spectrum of medical and surgical services and is recognized for its expertise in anesthesiology, cardiology, cardiographic surgery, general surgery, nephrology, neuroscience, obstetrics and gynecology, oncology, orthopaedics, pediatrics, plastic surgery, pulmonary medicine, trauma and transplant surgery. Allegheny serves as the western Pennsylvania campus of the Medical College of Pennsylvania, located in Philadelphia, and is a clinical site for MCP students. Through the Allegheny-Singer Research Institute (ASRI), hospital physicians have access to clinical and basic research facilities on campus. In addition to supporting clinical research, ASRI has an extensive animal research facility for applied and basic research projects.

The anesthesiology department maintains an active residency program and is responsible for the education of third and fourth year medical students, as well as subspecialty residents and fellows. Candidates should have achieved national recognition in educational, clinical and research activities. The position requires strong administrative, clinical and academic skills. Applicants should submit a curriculum vitae to: **George J. Magovern, M.D., Professor and Chairman of Surgery, ALLEGHENY GENERAL HOSPITAL and the ALLEGHENY CAMPUS of the MEDICAL COLLEGE of PENNSYLVANIA, 320 East North Avenue, Pittsburgh, PA 15212-9986.** Allegheny General Hospital is an equal opportunity/affirmative action employer.

MEDICAL COLLEGE OF PENNSYLVANIA

A Member of Allegheny Health, Education and Research Foundation

ALLEGHENY GENERAL HOSPITAL

Critical Care Physicians Harvard Medical School/Brigham & Women's Hospital

We are seeking a Co-Director of Surgical ICU/Director of the Critical Care plus four staff for the Critical Care Division of the Department of Anesthesia at the Brigham and Women's Hospital/Harvard Medical School.

Interested candidates should be Board Certified in Anesthesiology, or other primary specialty, with at least one year of Critical Care training in an ACGME certified program. Candidates should be Board certified or eligible in Critical Care.

Salary is competitive with an excellent benefit package. Qualified individuals should send curriculum vitae to:

Simon Gelman, M.D., Ph.D.
Chairman Department of Anesthesia
Brigham & Women's Hospital
Harvard Medical School
75 Francis Street
Boston, MA 02115

Harvard Medical School/Brigham & Women's Hospital are Equal Opportunity Employers.

— THE BEN COVINO RESEARCH AWARD —

Applications for up to $10,000 are invited for the 1993 Ben Covino Award, subject to the following basic conditions:

- The proposal should primarily relate to the use of local anesthetics/regional anesthesia, specifically within the preclinical and explorative clinical research fields.
- Applications to the Covino Award Committee must be received in the IARS Cleveland office no later than November 20, 1992. Where relevant, applications must include institutional approval of human studies and/or animal research.
- The official application for the Award must be used. This form, as well as the guidelines for applicants, is available on request to:

International Anesthesia Research Society
2 Summit Park Drive, Suite 140
Cleveland, OH 44131
USA
Telephone: (216) 642-1124

The establishment of the Ben Covino Award was announced at the 1992 Annual Scientific Meeting of the International Anesthesia Research Society held at the San Francisco Hilton. The Ben Covino Award has been instituted by Astra Pain Control, Sweden.

Achieve the
power of balance.

Now more than ever, the realities of anesthesia management require providing the highest standards of patient care while controlling costs.

At ASA 1992, see how Ohmeda can help you achieve this delicate balance in your anesthesia practice.

PAIN MANAGEMENT TRAINING

Changing directions?

Enter the highly gratifying specialty of Pain Management, offering both great professional and significant financial satisfaction. Six to twelve months training program is offered in a busy Private Practice Pain Center. Duration of training program depends on previous training in Pain Management.

Our center provides a combination of extensive clinical experience in a wide variety of procedures, medical and psychological management of pain and unique exposure to the business and administrative aspects of a large Private Practice Pain Management Center. Appropriate Candidates may be offered staff positions after training.

For more information send C.V. to:

Director of Neuroanesthesia University of California, San Francisco

The University of California, San Francisco, Department of Anesthesia invites application for the position of Director of Neuroanesthesia. Newly identified resources make this an outstanding opportunity. The applicant must be certified in anesthesia and have completed a neuroanesthesia fellowship and have extensive clinical and academic experience in neuroanesthesia. The candidate would be expected to develop an outstanding clinical and research fellowship program. Research funding, research space and possible tenure available.

Those interested applicants for this outstanding opportunity should send curriculum vitae to:

Ronald D. Miller, M.D.
Professor and Chairman,
Department of Anesthesia
UCSF, 521 Parnassus Ave.
Box 0648, Room C-455
San Francisco, CA 94143-0648

The University of California is an Equal Opportunity Affirmative Action Employer.

Intraoperative Transesophageal Saline-Contrast Imaging of Flow-Patent Foramen Ovale

Terence D. Rafferty, MD

Department of Anesthesiology, Yale University School of Medicine, New Haven, Connecticut

Estimates of the prevalence of patent foramen ovale, defined by the ability to pass a probe through the foramen at autopsy (probe patency), have ranged from 25% to 35% (1,2). The reported prevalence of detectable flow across the foramen ovale (flow patency) under in vivo resting conditions has ranged from 5% to 10% (3–8). The sensitivity of patent foramen ovale flow patterns to changes in loading conditions is evidenced by the marked increase in flow-patency detection rates (18%–22%) that can occur when the hemodynamic milieu is manipulated by such provocative interventions as sudden release of positive intrathoracic pressure (Table 1). In this issue of *Anesthesia & Analgesia*, Jaffe et al. (8) report an association between application of mechanical ventilation and positive end-expiratory pressure in normal anesthetized patients and transesophageal saline-contrast imaging of right-to-left flow across previously unsuspected foramen ovale, further illustrating the dynamic nature of these interatrial communications.

The normal mean interatrial pressure gradient is from left to right. As mentioned, a standard technique for reversing this gradient consists of sudden release of positive airway pressure (3–8). The rationale for this method is as follows: during application of positive pressure, intrathoracic pressure increases, causing a decrease in right atrial filling and transmural pressure. With release of the positive pressure, blood rushes into the right atrium, causing right atrial pressure to transiently exceed left atrial pressure (3). Further, two studies pertaining to the effects of positive end-expiratory pressure on central hemodynamics tabulate measured right atrial pressure, together with such indirect indices of left atrial pressure as pulmonary capillary wedge pressure and pulmonary artery diastolic pressure (9,10). In neither of these reports is there evidence of reversal of the mean right atrial-left atrial pressure gradient with application of positive end-expiratory pressure. Accordingly, the data of Jaffe et al. (8) appear, superficially, to conflict with conventional wisdom; however, other issues must also be considered. First, a right-to-left pressure differential at any phase of the cardiac cycle would be expected to result in a positive diagnosis. Right and left atrial pressure changes are asynchronous, and a transient reversal of gradient often occurs in early systole (11). Accordingly, analysis of mean pressure differentials may be misleading. Second, as emphasized by Jardin et al. (9), considerable individual variation exists in the hemodynamic response to positive end-expiratory pressure. Third, the foramen ovale is a flap valve, and altered cardiac geometry, with distortion of septal configuration, has been implicated in the genesis of flow patency of the foramen ovale after pneumonectomy (12). Finally, specific flow patterns within the right atrium may also influence flow across the septum. Swan et al. (13) have demonstrated that inferior vena cava venous return is normally preferentially directed toward the foramen ovale. In contrast, Langholz et al. (14) have reported a case where juxtaposition of a right atrial mass and the superior vena cava caused streaming of venous return toward a flow-patent foramen ovale that was ultimately associated with a fatal paradoxical embolus. As Jaffe et al. (8) state, a complete understanding of the factors affecting interatrial pressure gradients in the absence of preexisting pulmonary hypertension requires additional study.

The clinical implications of flow patency of the foramen ovale in patients undergoing surgery are well recognized. Flow patency has been characterized both as a risk factor for paradoxical embolization and as a possible cause of unexplained hypoxemia (12,15–18). Guggiari et al. (5) considered demonstration of a right-to-left shunt as representing an absolute contraindication to craniectomy in the sitting position. Black et al. (6) and Cucchiara et al. (15) also suggested that an evaluation of flow patency is an important part of the assessment of such patients, with intraoperative transesophageal echocardiographic definition

---

TEE, transesophageal echocardiography; VAE, venous air embolism.

allowing the clinician the choice of altering patient position before the operation has begun. Black et al. (19) have also recommended the avoidance of positive end-expiratory pressure in the sitting position. Their conclusions were based on data derived from an animal model with a surgically created atrial septal defect. The report by Jaffe et al. (8) consolidates this recommendation. Because of the prevalence of flow patency, the authors further suggest that any patient maintained on mechanical ventilation, particularly those requiring positive end-expiratory pressure, may be at particular risk for paradoxical embolization after inadvertent introduction of air at a wound or venous access site. Konstadt et al. (7) have addressed the circumstances of diagnosis of flow patency during an ongoing closed cardiac procedure, such as coronary revascularization. These authors have concluded that the additional surgical risk involved in closure of the defect may be justified in patients with a history of unexplained transient ischemic attacks for which paradoxical emboli may be the cause. Any such intraoperative decision must include an overall cardiac evaluation lest the foramen represent a functional left atrial decompression vent mitigating against pulmonary edema, as occurred in our institution in a case with mitral regurgitation, and a definitive decision may be deferred pending ventriculography. Finally, Vacek et al. (12) and Dewan et al. (18) have reported two instances where severe postoperative hypoxemia was definitively due to shunting through previously unsuspected foramen ovale.

The study of Jaffe et al. (8) utilized saline-contrast definition of a right-to-left shunt to delineate flow patency of the foramen ovale. This technique has the disadvantage that no right-to-left shunting may be apparent under basal conditions because the mean left atrial pressure normally exceeds that of the right atrium. A left-to-right shunt can be defined by saline-contrast imaging, the so-called negative saline-contrast technique (20). In this method, the shunt is inferred by visualization of an area without contrast within a contrast-containing right atrium. The "negative" area is due to displacement of contrast-containing blood by non-contrast-containing left atrial blood (20). Unfortunately, this finding can be subtle, particularly so under conditions of tachycardia (21). On the other hand, the appearance of contrast in the left atrium is unequivocal, and no further steps are required to establish the diagnosis (22). Black et al. (6) have stated that the sensitivity of transesophageal echocardiography is such that the likelihood of clinically significant paradoxical embolism not being imaged is remote with this form of monitoring. However, it must be stressed that saline-contrast diagnostic studies of atrial septum integrity may often be associated with false-negative results, even when performed in association with a provocative maneuver (Table 2). Accordingly, although a positive test is definitive, a negative diagnostic study does not preclude subsequent flow patency.

It is generally accepted that echocardiography is an operator-dependent technique. Accurate diagnosis is

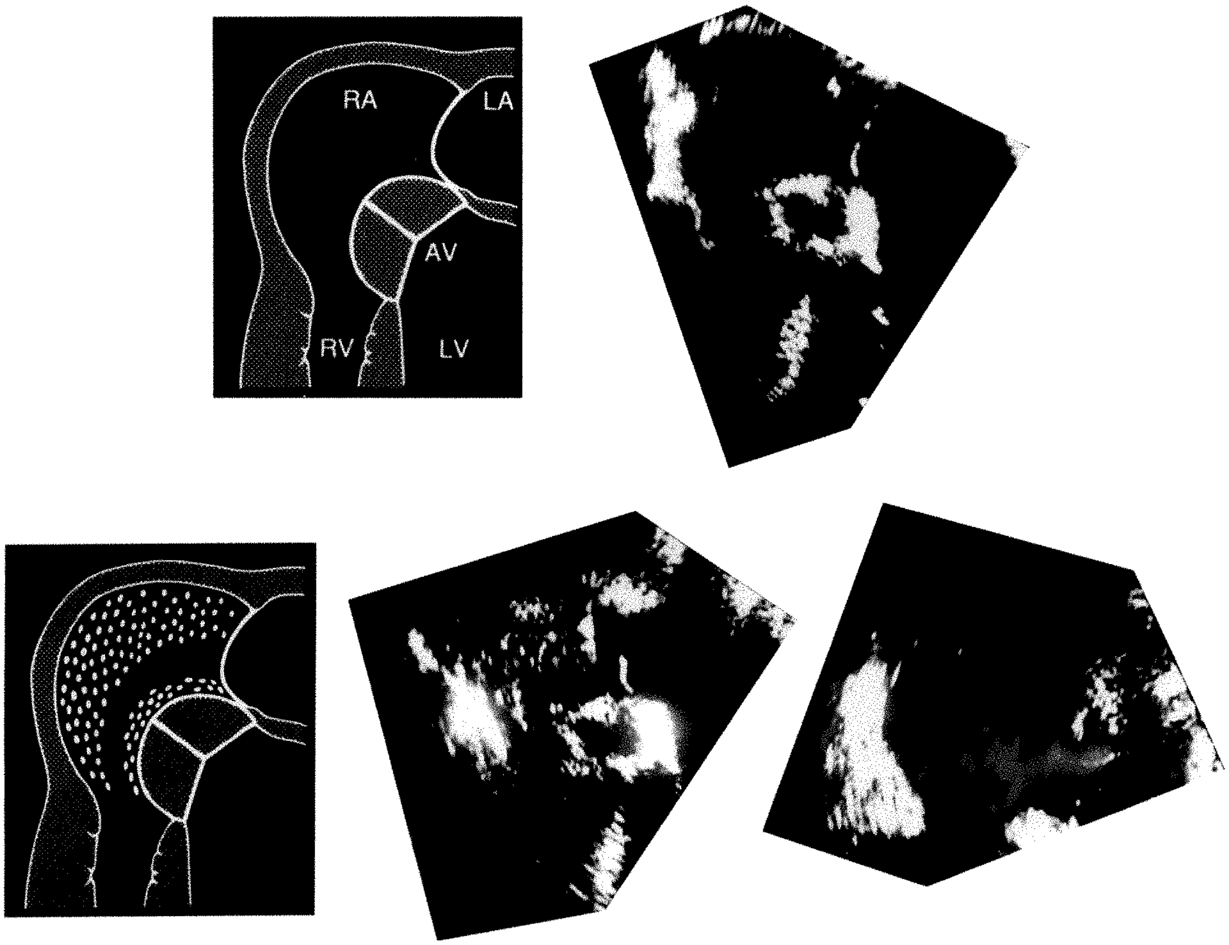

Figure 1. Patent foramen ovale with negative saline-contrast diagnosis of left-to-right shunt. *Upper panels,* Representation of left-to-right interatrial pressure gradient evidenced by bowing of the septum to the right. *Lower left and middle panels,* Left atrial blood containing no contrast has displaced the contrast-containing blood in the right atrium. *Lower right panel,* The area of negative saline-contrast in the lower left and middle panels corresponds to the color-flow-Doppler-defined left-to-right flow. RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; AV, aortic valve.

inexorably tied to performance of a technically adequate examination (23). Performance of a complete saline-contrast evaluation of the foramen ovale involves two-dimensional echocardiographic analysis of the atria in conjunction with intravenous administration of hand-agitated saline, timed to achieve right atrial opacification with the agitated saline synchronous with sudden release of positive airway pressure. Although such general factors relating to acquisition of quality images as optimization of coarse and time-gain settings are pertinent, there are technical considerations specific to (a) imaging of the atria, (b) production of adequate opacification, and (c) definition of the appropriate level of airway pressure to be used in any provocative maneuver. Seward et al. (24) have noted that the atrial septum is evident in multiple short- and long-axis transesophageal transverse plane tomographic projections. These authors have defined a comprehensive transverse plane assessment as encompassing both a biatrial cephalad basal short-axis scan at aortic valve level and a more caudad long-axis four-chamber view (24). Biplane imaging provides the capacity to examine the atria and septum in a longitudinal plane. Longitudinal plane views image extreme anterior and posterior structures and provide access to the atrial septum along its greater length (25,26). This can be particularly useful in the setting of aortic root dilation, where the septum can appear especially shortened on short-axis imaging (26). Clearly, a thorough examination with technically acceptable images demands a degree of expertise.

An appreciation of the technical limitations of saline-contrast imaging demands an understanding

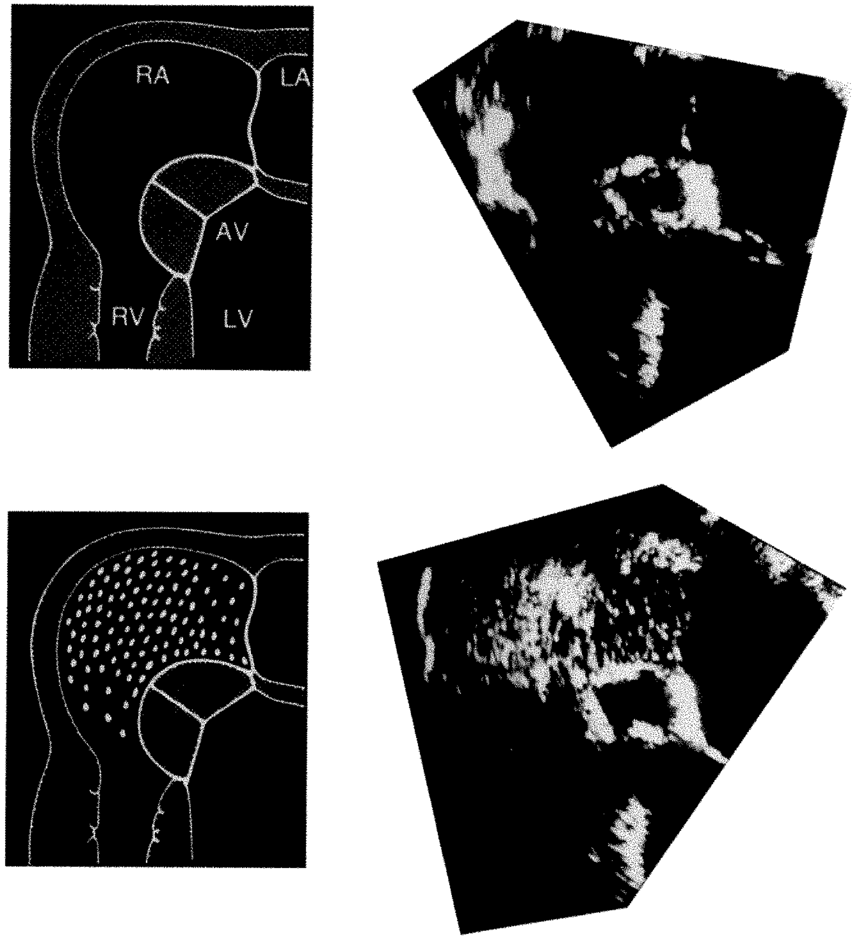

Figure 2. Patent foramen ovale with conditions of zero flow. *Upper panels,* The interatrial septum can be seen to have assumed a midline position, reflecting the absence of a pressure gradient between the atria. *Lower panels,* Saline-contrast imaging does not depict the septal defect, emphasizing the importance of utilizing an endpoint to avoid false-negative diagnoses.

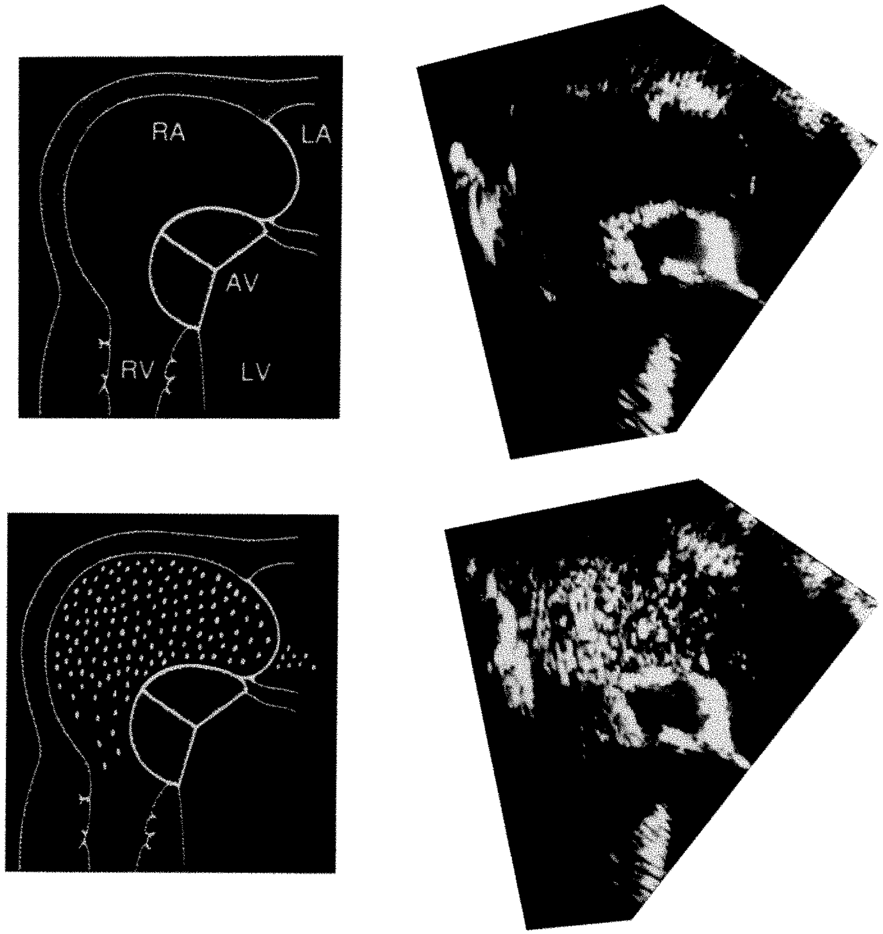

Figure 3. Patent foramen ovale with saline-contrast definition of a right-to-left shunt. *Upper panels,* Representation of a right-to-left interatrial pressure gradient evidenced by bowing of the septum to the left. *Lower panels,* Saline-contrast can be seen to traverse the septum into the left atrium.

of the mechanism whereby injected saline can function as an ultrasound-opaque medium and thus opacify intracardiac structures. Rapid injection of any gas-containing solution through a small-bore orifice causes microbubbles to form within the solution. This microbubble formation is a consequence of the pressure decrease at the orifice (Bernouilli principle) that allows the dissolved gases to escape from solution (21). These microbubbles within the saline provide the source of contrast. Saline-contrast echocardiography represents an echocardiography imaging method whereby microbubbles are intentionally produced by preinjection agitation of saline. With peripheral venous (rather than central) injection of hand-agitated saline, the microbubbles within the solution may have redissolved too rapidly to be of diagnostic value. In addition, the transit time within the atrium in patients with normal hemodynamics may be so brief as to make it difficult to synchronize adequate chamber opacification with the various manipulations of intrathoracic pressure. Parenthetically, patients with depressed right ventricular function or tricuspid incompetence are technically less challenging, owing to decreased transit time in the former situation and "reconcentration" of the contrast by the regurgitation in the latter instance (27,28). Finally, the effects of the various manipulations of airway pressure may not be sufficient to induce a right-to-left gradient under the conditions of the saline-contrast study, owing to such factors as adequate right ventricular reserve or a disproportionate baseline left atrial pressure. With changing clinical circumstances, the differential between right and left heart pressures may then allow paradoxical embolization or indeed cause clinically meaningful right-to-left shunt-associated hypoxemia. As emphasized by Konstadt et al. (7), confidence in negative results requires documentation that the release of positive airway pressure has indeed created a pressure-gradient reversal. In one patient in their series, there was no shunting during apnea or after release of 20 cm H_2O positive airway pressure. It was noted that the right atrial pressure did not exceed the pulmonary capillary wedge pressure at any time during the cardiac cycle. Contrast injection was repeated after release of 30 cm H_2O positive airway pressure, a step that resulted in transient elevation of right atrial pressure over pulmonary capillary wedge pressure and right-to-left shunting of contrast. These authors have recommended that the anatomic configuration of the atrial septum be used as an endpoint for assessing the efficacy of interventions used to induce a right-to-left gradient. The compliance of the septum is such that even minor changes in pressure differential that normally occur during a cardiac cycle are reflected by detectable changes in spatial orientation (29). Accordingly, it would seem prudent to visually confirm leftward displacement of the septum before cases are accepted to have a negative saline-contrast study result. These technical aspects are illustrated in Figures 1–3, representing an incidental patent foramen ovale in a 68-yr-old patient undergoing coronary artery bypass graft surgery, whereby a left-to-right shunt, zero flow, and a right-to-left shunt were evoked by manipulation of airway pressure. Accordingly, although it is clear that saline-contrast evaluation of the integrity of the atrial septum should be part of minimal reporting requirements during intraoperative transesophageal echocardiographic monitoring, complementing color flow and pulsed Doppler examinations, it is essential that imaging limitations be recognized.

Venovenous Bypass During Liver Transplantation

Scott D. Kelley, MD

Department of Anesthesia, University of California—San Francisco, San Francisco, California

In this issue of *Anesthesia and Analgesia*, Veroli and colleagues (1) explore an important aspect of the intraoperative management of liver transplantation: the use of venovenous bypass hemodynamic support during the anhepatic period. Liver transplantation is an effective therapy for a variety of acute and chronic liver diseases that result in hepatic failure. Much of the improvement in survival statistics can be attributed to advances in immunosuppressive management, particularly the introduction of cyclosporine and the earlier recognition of rejection episodes. However, despite nearly 30 yr of clinical experience in human liver transplantation, the intraoperative management of this procedure remains challenging for anesthesiologists and surgeons. The magnitude of the surgical procedure (i.e., total hepatectomy, porta hepatis dissection, four major vascular anastomoses, and biliary reconstruction) in patients with severe liver disease (i.e., portal hypertension, coagulopathy, and thrombocytopenia) accounts for much of the difficulty encountered with this procedure. In addition, the critical part of the operation, the anhepatic period, requires the vascular exclusion of the liver to permit anastomosis and subsequent reperfusion of the hepatic allograft. This time period (30–90 min) is marked by significant changes in cardiovascular indices: decreased filling pressure, decreased cardiac output, increased infrahepatic caval pressure, decreased renal perfusion pressure, and moderately decreased systemic arterial pressure. To attenuate some of these hemodynamic responses, venovenous bypass was introduced to facilitate venous return of blood from the lower extremities and portal system to the upper body (2). Additional perioperative benefits attributed to venovenous bypass include decreased bleeding and transfusion requirement, improved postoperative renal function, decompression of the intestinal vascular bed, and earlier return of intestinal function; a better environment in which to train transplant surgeons is also an important benefit (3). Because the potential benefits of venovenous bypass appear to be significant, many transplant centers have adopted routine use of bypass during liver transplantation. However, there is an increasing number of case reports and clinical experience that associate significant complications with the use of the bypass technique: air embolism, thromboembolism, trauma to the brachial plexus and cannulated vessels, increased surgical time, and increases in incidence and severity of hypothermia (4,5).

Ideally, the overall benefits of venovenous bypass should be assessed by measuring specific outcome variables in randomized clinical trials. Hemodynamic instability, although worrisome to clinicians, is not a precise outcome; renal failure, blood product utilization, early graft function, and patient morbidity and mortality are among the important outcome variables to assess. Presently, no outcome studies are available to evaluate the benefits of venovenous bypass. Transplant centers and physicians must evaluate their use of this technique by balancing the benefits of this technique against the risks. Currently, the use of venovenous bypass at different centers ranges from never to universal application in adult patients. With the increasing frequency of liver transplantation, it is essential that we evaluate closely the potential benefits and adversities associated with venovenous bypass.

Veroli and colleagues (1) examine one of the purported benefits of venovenous bypass: preservation of postoperative renal function. Perioperative renal function is a complicated issue in patients undergoing liver transplantation. Preoperatively, patients with end-stage liver disease may manifest renal dysfunction. The etiology of preoperative renal dysfunction includes the usual differential diagnoses; in addition, the hepatorenal syndrome may be evident in 10%–15% of patients presenting for liver transplantation. Intraoperatively, the kidney is subjected to a variety of insults that may impact on postoperative function: dramatic changes in hemodynamics, alterations in renal perfusion pressure, and cyclosporine administration. Postoperatively, the kidney is vulnerable to additional insults, particularly those caused by the use of cyclosporine and other nephrotoxic agents. Several studies have documented a reduction of

approximately 30%–40% in glomerular filtration rate after liver transplantation in patients with previously normal renal function. Postoperative renal failure is particularly deleterious in liver transplant patients and has been associated with an extremely high perioperative mortality (6). Previous investigators have explored other avenues of renal protection, including intraoperative dopamine (7) and verapamil (8), but have been unable to attenuate postoperative renal dysfunction.

Venovenous bypass may modulate postoperative renal dysfunction. As indicated earlier, it is known to ameliorate some of the acute hemodynamic changes during the anhepatic period and can usually preserve normal renal perfusion pressure during this stage (8–10). However, because the kidneys are subject to multiple insults in the perioperative period of hepatic transplantation, simply maintaining normal systemic and renal hemodynamics may not be sufficient to prevent postoperative renal dysfunction.

Interpreting the results of the Veroli et al. (1) study requires particular attention. Their study design was limited by the patterns of care within the institution: they believed it necessary to provide venovenous bypass support to patients who developed marked hemodynamic instability (a decrease in mean arterial pressure >30% or a decrease in cardiac index >50%, or both) in response to a trial period of hepatic vascular occlusion. They also believed that the possible risks of bypass prevented random assignment of the technique to patients who did not require it for cardiovascular support. Nonetheless, their study provides results important for anesthesiologists and surgeons involved in these procedures. Specifically, use of the trial period of hepatic vascular occlusion permitted identification of two distinct populations of patients undergoing liver transplantation. Patterns of collateral flow or degrees of reflex responsiveness to hepatic vascular exclusion, or both, are likely to have been different in patients who tolerated the trial within the limits assigned and in those unable to maintain blood pressure or cardiac index. Readers must recognize that the limits selected by Veroli et al. (1) were arbitrary; there have been no prospective studies performed to determine the deleterious effects, if any, of the changes in arterial pressure or cardiac index.

Nevertheless patients were assigned to two separate groups, and venovenous bypass support was utilized in the patients with marked hemodynamic changes in response to the test clamp. Veroli et al. (1) were unable to discern a significant difference in postoperative renal function (as measured by serum creatinine on the third postoperative day) despite significant differences in the renal hemodynamics and urine output during the anhepatic phase. These findings allow us to conclude that patients with normal renal function preoperatively, and who tolerate the trial period of hepatic vascular exclusion, do not require the use of venovenous bypass to prevent postoperative renal failure. In addition, patients managed without bypass did not require increased intraoperative blood products support compared with patients in whom bypass was used.

It is important to realize the additional, and perhaps most significant, limitations of this study. The use of bypass in the patients who did not appear to "require" bypass for hemodynamic support was not tested. It is possible that if these patients had received bypass support, their renal function or blood loss, or both, might have been better. Similarly, the value to outcome in maintaining arterial blood pressure and cardiac index in patients who were supported with bypass was not fully assessed. The data presented by Veroli et al. (1) are insufficient to determine whether the patients who demonstrated moderate hemodynamic instability during the trial period of hepatic vascular exclusion benefited from the use of venovenous bypass. Readers of the Veroli et al. (1) study will be unable to conclude whether the use of bypass in these patients was necessary to preserve renal function or whether the only impact was on the measured hemodynamic variables that Veroli et al. (1) report.

In an ideal study, a random assignment to venovenous bypass support would provide answers to many questions with regard to the purported benefits of this technique. As mentioned in the report by Veroli et al. (1), such a study would require a very large number of patients to avoid a type II error. Specifically, given the incidence of postoperative renal dysfunction and an anticipated benefit from venovenous bypass of 50% (i.e., that the incidence of postoperative renal dysfunction would be reduced from 20% to 10%), an adequate study would require approximately 700 patients. Studies lacking adequate sample size are at risk for declaring no benefit from venovenous bypass when, in fact, a benefit did exist. Similarly, although Veroli et al. (1) found no demonstrable evidence of a difference in renal function in patients managed with or without venovenous bypass, they were unable to claim that venovenous bypass is without benefit.

In summary, this study, despite its limitations, suggests an important change for the management of hepatic transplantation. In a single institution, the selective utilization of venovenous bypass support based on a trial period of hepatic vascular exclusion did not have an adverse impact on postoperative renal function, surgical duration, or transfusion requirement. Additional centers should consider future studies designed to identify which patients, if any, need or will benefit from venovenous bypass support. Until such studies are performed, Veroli et al. (1) have provided good evidence that routine and systematic use of venovenous bypass is not an absolute requirement.

Aspects of Mechanical Ventilation Affecting Interatrial Shunt Flow During General Anesthesia

Richard A. Jaffe, MD, PhD, Fausto J. Pinto, MD, Ingela Schnittger, MD,
Lawrence C. Siegel, MD, Bengt Wranne, MD, PhD, and John G. Brock-Utne, MD, FFA(SA)
Departments of Anesthesia and Internal Medicine (Cardiology Division), Stanford University School of Medicine, Stanford, California

Intraoperative transesophageal echocardiography was used to study the incidence of flow-patent foramen ovale in 33 normal, healthy patients (ASA physical status I) undergoing general anesthesia in the supine position for nonthoracic surgical procedures. Echocardiographic contrast was injected intravenously during mechanical ventilation in the presence of 0, 5, 10, 15, or 19 cm H_2O positive end-expiratory pressure (PEEP). A final test was performed during the release of 19 cm H_2O PEEP. The presence of a flow-patent foramen ovale was detected when the injected echo targets were observed crossing the interatrial septum from right to left. Most interesting, 3 of 33 patients developed a right-to-left shunt that was first detected with the steady application of 10 (1 patient) or 15 cm H_2O PEEP (2 patients). In all three cases, the shunt flow was accentuated on the release of PEEP; however, no additional cases were detected using this respiratory maneuver. These cases represent the first demonstration of right-to-left interatrial shunting evoked as the result of the sustained application of PEEP. This study also revealed a lower than expected incidence of flow-patent foramen ovale (9%) when measured during general anesthesia and positive pressure ventilation with or without PEEP.

(Anesth Analg 1992;75:484–8)

The incidence of venous air embolism (VAE) during general or regional anesthesia in the supine position has been reported for a variety of surgical procedures, including craniectomy (41%–66%) (1,2), cesarean section (50%) (3), and hip replacement surgery (30%) (4). Although the likelihood of VAE during these procedures is substantial, clinical manifestations of VAE are often undetectable, because the volume of embolized air is small and the filtering capacity of the lungs is rarely exceeded.

Paradoxical VAE can occur when air crosses from the systemic venous to the systemic arterial circulation without passing through the pulmonary capillary filter. Most commonly, crossover is believed to occur through a patent foramen ovale (PFO). On the basis of an extensive autopsy series (5), the incidence of probe-PFO in an adult population is 27% (range 19%–36%), with the highest incidence found during the first three decades of life. Thus, a significant percentage of patients, as high as 24% (i.e., 36% of the 66% incidence of VAE seen in supine craniectomies), undergoing selected surgical procedures in the supine position are at risk for paradoxical VAE, with its consequent risk of cerebral or myocardial embolization and infarction (6,7).

The preoperative identification of patients at risk for paradoxical VAE has been the subject of several recent echocardiographic studies that reported prevalence rates of 6%–18% (7–10). However, the sensitivity and specificity of precordial echocardiography in preoperative screening may not be adequate to identify every patient at risk for paradoxical VAE (11,12). For example, several studies utilizing screening tests with precordial Doppler failed to identify patients in whom paradoxical embolism did occur (9,13,14). Although the relative merits of the various preoperative screening methods can be debated, it is clear that high priority should be given to the identification of those factors that can affect interatrial shunt flow in the anesthetized patient. In this way, it may be possible to enhance patient safety while minimizing the need for preoperative screening tests.

The use of mechanical ventilation with or without positive end-expiratory pressure (PEEP) is common during general anesthesia and in the intensive care unit setting. The release of high levels of PEEP (analogous to the release of a Valsalva maneuver) can evoke shunt flow through a PFO. Unknown, how-

ever, is the extent to which cyclic intrathoracic and airway pressure changes produced during mechanical ventilation may repeatedly mimic the pressure changes produced on the release of PEEP. Thus, it is possible that mechanical ventilation may produce recurring opportunities for right-to-left interatrial shunt flow with the attendant risk for paradoxical embolization.

The goals of the present study were (a) to examine the effects of mechanical ventilation and sustained PEEP on the occurrence of right-to-left interatrial shunt flow during general anesthesia in a healthy patient population undergoing general surgery, and (b) to describe the incidence of PFO using a traditional respiratory maneuver (PEEP release) and transesophageal echocardiography (TEE) in this same population.

Methods

This study was approved by the Stanford University Medical Committee for the Protection of Human Subjects in Research, and written consent was obtained from all subjects. Thirty-three patients (13 male, 20 female; mean age 32 yr; range 21–55 yr; ASA physical status I) scheduled for nonthoracic surgery in the supine position were included in this study. Excluded from this study were patients with any history of cardiovascular, pulmonary, or esophageal disease. The conduct of anesthesia was left to the judgment of each patient's attending anesthesiologist, who played no part in the study. Typically, anesthesia was induced with thiopental (3–5 mg/kg IV) and maintained with a combination of isoflurane in an oxygen/nitrous oxide mixture. Tracheal intubation was accomplished after administration of a muscle relaxant, and muscle relaxation was maintained with a nondepolarizing agent. Routine monitoring included electrocardiography, noninvasive blood pressure monitoring, pulse oximetry, capnography, and mass spectrometry.

All ultrasound recordings were obtained using a Hewlett-Packard ultrasonograph (model Sonus 500, Andover, Mass.) with a 5-MHz single-plane transducer mounted at the tip of a 14-mm flexible adult gastroscope (model 21362A, Hewlett Packard echoscope). All studies were performed within the first hour of general anesthesia, with the patient in a supine position. The TEE probe was introduced into the esophagus with the transducer facing anteriorly. Tomographic planes were obtained in the usual fashion by translating and rotating the echoscope within the esophagus while observing the ultrasonic image for reference (15). Modified four-chamber (biatrial) views were used to allow optimal visualization of the interatrial septum and left and right atria. All of the echocardiographic examinations were performed by experienced echocardiographers.

Each subject was tested during the sustained application (>30 s) of 0, 5, 10, 15, and 19 cm H_2O PEEP during mechanical ventilation using a tidal volume of 10–15 mL/kg at a frequency of 6–10 breaths/min. The final test was performed during the release of 19 cm H_2O PEEP. Echo contrast was produced by the vigorous agitation of 10 mL of saline with a small volume of air using a two-syringe technique (creating microbubble echo targets). After excluding macroscopic bubbles, the saline was rapidly injected into a peripheral vein of an upper extremity. A contrast injection was deemed adequate only if the right atrium became completely opacified by echo targets. This often required more than one injection. A test was considered positive if injected echo targets were observed to cross the interatrial septum from right-to-left. All TEE data were recorded on videotape and subsequently analyzed by an independent echocardiographer.

Results

Right-to-left interatrial shunt flow was observed in 3 (9%) of 33 healthy patients during mechanical ventilation and general anesthesia for noncardiac surgery (Figure 1). In one of these patients, as previously presented in a case report (16), episodic interatrial shunt flow was observed coincident with early inspiration at 0, 5, and 10 cm H_2O PEEP, becoming independent of respiratory phase at higher levels of PEEP. Shunt flow in the other two patients was not observed in the absence of PEEP, but was first detected during the steady application of 10 and 15 cm H_2O PEEP. In these two cases, there was no obvious relationship between the septal crossing of echo targets and a specific phase of the respiratory or cardiac cycles. In the remaining 30 patients, there was no evidence of interatrial shunt flow during mechanical ventilation without PEEP or with constant PEEP up to 19 cm H_2O. The release of high levels of PEEP, a traditional respiratory maneuver used to provoke interatrial shunt flow in a manner analogous to Valsalva release, failed to permit TEE detection of any additional patients with PFO.

The three patients testing positive for flow-PFO could not be distinguished from the other 30 patients on the basis of anesthetic technique, surgical procedure, airway pressures during mechanical ventilation, or any other monitored variable. Additionally, TEE measurements of right atrial and ventricular dimensions in these patients were within normal limits.

Direct verification of PFO in our patient population was not possible, and thus an estimation of the true

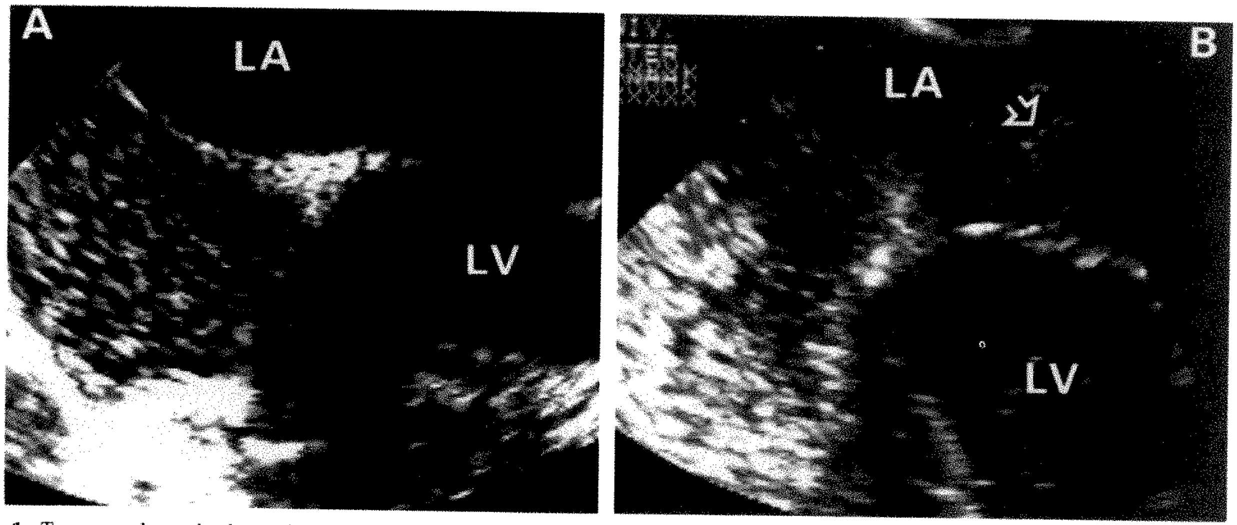

Figure 1. Transesophageal echocardiogram of a patient (**A**) during intermittent positive pressure ventilation and (**B**) during the application of 10 cm of positive end-expiratory pressure. *Arrow*, targets in the left atrium (LA) denoting interatrial shunting; LV, left ventricle. *Unlabeled chambers in the lower left corner* filled with echo targets are the right atrium and right ventricle.

detection rate of TEE for PFO was beyond the scope of this study.

Discussion

The ability to identify patients at risk for paradoxical embolization through a PFO and to characterize specific factors that affect flow through a PFO are of considerable interest to anesthesiologists. Previously reported preoperative screening studies using precordial (transthoracic) echocardiography have been characterized by both low sensitivity and false-negative results (7,14). Contrast imaging with TEE is superior to transthoracic imaging for the detection of PFO (11). Pearson et al. (11) studied 79 patients presenting with unexplained stroke or transient ischemic attacks and compared transthoracic echocardiography with TEE. A PFO was more frequently identified by TEE (9 vs 1 of 79 patients; $P < 0.005$). In a similar study at our institution (12), 4 of 50 patients with recent transient ischemic attack or embolic stroke and normal transthoracic echocardiograms had TEE-detectable PFOs. These findings, confirmed by other investigators (15), demonstrate that contrast two-dimensional (single-plane) TEE is presently the definitive diagnostic technique for PFO detection. The possibility that the single plane of view afforded by two-dimensional TEE may miss crossing echo targets remains of some concern. Recently, biplane and omniplane TEE probes have been introduced into clinical practice (17). Future studies may demonstrate that these devices can enhance the visualization and detection of PFO.

Konstadt et al. (18), in a recently published study of 50 patients with severe cardiovascular disease, using both TEE and Doppler techniques, reported a 26% incidence of *flow*-PFO. These results closely approximate the overall prevalence of *probe*-PFO (25%–27%) from autopsy studies (5,19), and this is the only echocardiographic study to demonstrate this high sensitivity. In the present study, using techniques very similar to those of Konstadt et al. (18), the incidence of flow-PFO in a healthy general surgical population was only 9%. The respiratory maneuver used to provoke shunt flow (release of 19–20 cm H_2O positive airway pressure) was similar in both studies. Konstadt et al. (18) attributed the high detection rate of their TEE technique to four factors that distinguished their study from those previously reported. The first three factors were identical in both studies. Specifically, the heart was imaged using a biatrial view to provide optimal visualization of the interatrial septum (20); second, a vigorous two-syringe technique was used to agitate the saline for the production of high-density microbubble echo targets; and third, complete opacification of the right atrium was assured before a test was considered valid. The fourth factor was their use of pulse-wave and color-flow Doppler techniques. Using these techniques, they were able to detect right-to-left interatrial shunt flow in one additional patient with shunt flow previously undetected by conventional contrast TEE. Overall, however, the color flow Doppler was found to be a much less sensitive technique, detecting only 3 of the 12 patients with right-to-left interatrial shunting (18).

In the absence of any significant technical or operator differences, we believe that the uniquely high detection rate of TEE in the Konstadt et al. (18) study may be related simply to differences in patient populations and the small sample size in both studies. In the present study, only healthy adults undergoing elective nonthoracic surgical procedures were included. In contrast, the Konstadt et al. (18) study patients all had evidence of cardiovascular disease, with 45 of the 50 patients (and 11 of the 12 patients with right-to-left shunt flow) presenting for coronary revascularization or valve replacement, or both. Perhaps myocardial function was altered in these patients in a way that could increase the probability for reversal of the normal left-to-right interatrial pressure gradient or could affect the normal valve characteristics of a probe-PFO. Although these patients should have elevated left atrial pressures, subtle changes in atrial dimensions, myocardial contractility, or conduction pathways may have offsetting effects on the instantaneous interatrial pressure gradient and thus on the functional patency of the foramen ovale.

Anatomic or probe patency, although necessary, may not be sufficient to ensure the physiologic or flow patency of the foramen ovale. The unidirectional flap-valve nature of the foramen ovale requires at least the transient reversal of the normal left-to-right interatrial pressure gradient to permit shunt flow. Persistent reversal of this interatrial pressure gradient is usually associated with right heart outflow obstruction and right atrial volume overload. Transient reversal of the gradient can occur with release of sustained airway pressure (e.g., after a Valsalva maneuver or the release of PEEP). During the strain phase of a Valsalva maneuver or during the sustained application of PEEP, intrathoracic pressure increases, transiently causing right atrial pressure to decrease (secondary to decreased venous return). Then, on release of the Valsalva maneuver or PEEP, venous return to the heart suddenly increases, causing a transient increase in right atrial pressure (as much as 20 mm Hg) (21) with the potential for reversal of the normal interatrial pressure gradient. Langholz et al. (22) recently identified in three patients three different mechanisms for right-to-left flow through a PFO in the absence of elevated pulmonary artery or right atrial pressures: (a) transient reversal of the normal interatrial pressure gradient with each cardiac cycle; (b) preferential streaming of superior vena cava blood entering the right atrium directed at the foramen ovale, producing a localized increase in pressure at that site sufficient to permit shunt flow; and (c) release of 20 cm H_2O PEEP, causing right atrial pressure to increase above left atrial pressure. It is likely that the first two mechanisms operate continuously in all normal persons to at least reduce the magnitude of the interatrial pressure gradient and thus increase the probability of right-to-left shunt flow. For example, in the patient exhibiting the second mechanism described by Langholz et al. (22), the superior vena cava blood flow was directed at the foramen ovale as the result of a large right atrial mass; however, in normal adults, blood returning to the heart via the inferior vena cava is normally directed at the foramen ovale as a persistent anatomic consequence of fetal circulation. Thus, the generation of highly localized atrial septal pressure zones occurs normally but would be difficult to measure by conventional techniques.

The capacity of provocative respiratory maneuvers to cause paradoxical shunt flow may depend simply on the magnitude of the pressure gradient across the foramen ovale at the time of testing. For example, patients with small gradients may exhibit pressure reversals with each respiratory or cardiac cycle (23), whereas in others with large gradients, even the release of 20 cm H_2O PEEP or a Valsalva maneuver may not produce a sufficient increase in right atrial pressure to cause reversal of the normal interatrial gradient.

Somewhat more difficult to explain mechanistically is our observation that the sustained application of PEEP at 10–15 cm H_2O during mechanical ventilation was sufficient to permit right-to-left interatrial shunt flow in all three patients testing positive for flow-PFO using standard respiratory maneuvers. This observation may be explained by hypothesizing that sustained positive airway pressure will eventually increase right atrial pressure relative to left atrial pressure, possibly through an effect on pulmonary vascular resistance, thereby further reducing or reversing the interatrial pressure gradient. Perkins and Bedford (24) reported that right atrial pressure was increased by the application of 10 cm H_2O PEEP and exceeded pulmonary artery wedge pressure (and, by inference, left atrial pressure) in 7 of 11 patients studied while anesthetized in the sitting position. However, more recent studies in both humans (25) and dogs (26) failed to demonstrate any significant effect of 10 cm H_2O PEEP on the absolute interatrial pressure gradient, although 20 cm H_2O PEEP did reverse the interatrial pressure gradient in one of eight patients tested (25). A complete understanding of the factors affecting interatrial pressure gradients will require additional study.

In summary, we have reported the first demonstrations of right-to-left shunt flow evoked as a result of the sustained application of PEEP during general anesthesia. Our results suggest that patients exhibiting intrinsic PEEP or any patient on mechanical ventilation and especially those patients requiring PEEP, such as those in an intensive care unit setting, may be at increased risk for paradoxical embolization after the inadvertent introduction of even small quantities of air at a wound or vascular access site. Furthermore, we would not advocate the use of PEEP in an attempt to decrease the risk of VAE because of the probable increased risk for paradoxical embolization. Finally, we believe that the conventional respiratory maneuvers used to evoke interatrial shunt flow are inadequate in many cases. The ideal provocative maneuver should mimic the changes induced by VAE, specifically producing a sudden increase in pulmonary artery pressure with consequent increase in right heart pressures and subsequent decrease in left heart pressures. Future studies should focus on mechanisms that control the physiologic patency of the foramen ovale. This information will be of considerable clinical importance in the intraoperative and intensive care unit management of many patients.

We thank Audrey Stevens for help in preparing this manuscript.

Does Adult Liver Transplantation Without Venovenous Bypass Result in Renal Failure?

Philippe Veroli, MD, Christine El Hage, MD, and Claude Ecoffey, MD

Département d'Anesthésie-Réanimation, Hôpital Paul Brousse, Université Paris-Sud, Villejuif, France

Thirty-eight adult orthotopic liver transplant recipients were studied to compare renal hemodynamics and renal function with (17 patients) and without (21 patients) venovenous bypass. Bypass was used when mean arterial blood pressure decreased by >30% or cardiac index decreased by >50%, or both, during a 5-min trial of clamping of the suprahepatic and infrahepatic vena cava and portal vein. Intraoperative measurements were performed 2 h after induction of anesthesia, 10 min before the end of the anhepatic phase, and 2 h after cava unclamping. During the anhepatic stage, renal perfusion pressure decreased significantly in the group with no bypass (79 ± 20 vs 60 ± 17 mm Hg, $P < 0.05$) (mean ± SD), whereas it remained unchanged in the group with bypass (77 ± 14 vs 74 ± 16 mm Hg, NS); urinary output was not modified in the bypass group, whereas it decreased significantly in the group with no bypass compared with the dissection phase (0.7 ± 0.6 vs 1.7 ± 2.0 mL·kg^{-1}·h^{-1}, $P < 0.05$). However, during the postreperfusion phase, urinary output was similar in both groups and was more when compared with the dissection phase ($P < 0.05$). Serum creatinine level was increased in both groups on the third postoperative day, but no difference occurred between the groups (bypass group 107 ± 49 mmol/L; nonbypass group 126 ± 95 mmol/L). No patient required dialysis in either group in the postoperative period. This study suggests that in patients without preoperative renal failure and who tolerate the trial of clamping well, venovenous bypass is not required to maintain postoperative renal function after liver transplantation.

(Anesth Analg 1992;75:489–94)

Advances in surgical technique, anesthetic management, and postoperative care have resulted in improved survival rate after orthotopic liver transplantation (OLT). Among the numerous complications threatening the transplant patient, postoperative renal failure is a frequent and severe event, because it jeopardizes survival (1–3). This may be due to many factors, including intraoperative renal hypoperfusion, sepsis, and administration of potentially nephrotoxic drugs, such as antibiotics and cyclosporine A (2–4). The major blood loss occurring during the perioperative period appears to be an important factor of renal impairment (1), because hemorrhage may result in hypotension and sympathetic vasoconstriction, mainly affecting the afferent glomerular arterioles and causing a decrease in renal blood flow (5). During the anhepatic phase, the increase in inferior vena cava pressure is responsible for a decrease in renal perfusion pressure (6,7). Because a higher incidence of renal failure may occur when venous bypass is not used, its routine use has been advocated to improve early postoperative renal function (8). The aim of this study was to compare renal hemodynamic variations during OLT with and without bypass and to evaluate their consequences on perioperative urinary output and early postoperative renal function.

Methods

During a 5-mo period, 38 adult patients scheduled for a first OLT were studied. This study was approved by our Clinical Research Committee. All patients had normal preoperative renal function, assessed by a serum creatinine (SCr) value <120 μmol/L. Three phases can be identified in the surgical procedure of an OLT. During the dissection phase, the diseased liver is "skeletonized," leaving it with its vascular pedicles intact. The anhepatic phase begins after clamping of all the hepatic vessels; the diseased liver is removed entirely, and the vessels of the donor liver are anastomosed to those of the recipient. When the anastomoses of the portal vein and the vena cava are completed, the vascular clamps are released, and the

liver is reperfused with portal blood. In our institution, completion of the anastomoses of the hepatic artery and the biliary duct are performed after cava and portal vein reperfusion. All patients were orally premedicated with hydroxyzine (2 mg/kg) 60 min before induction of anesthesia. Anesthesia was induced with thiopental (5 mg/kg) and maintained with a continuous infusion of fentanyl (10 $\mu g \cdot kg^{-1} \cdot h^{-1}$) and midazolam (50 $\mu g \cdot kg^{-1} \cdot h^{-1}$) intravenously. Vecuronium was administered for muscle relaxation. The lungs were ventilated mechanically with a warmed humidified air/oxygen mixture to maintain the end-tidal CO_2 concentration between 30 and 35 mm Hg (Capnomac, Datex), O_2 saturation of arterial blood (Sa_{O_2}) >97%, and pH >7.30. No volatile anesthetic was used. Patients received transfusions of packed red blood cells and fresh-frozen plasma to maintain hemodynamic stability (i.e., mean pulmonary arterial pressure >18 mm Hg or pulmonary artery wedge pressure >12 mm Hg, or both, before the trial of clamping; change in mean arterial pressure <20% during the anhepatic phase) and a hematocrit at 30%. No other fluids (i.e., crystalloids or colloids) were administered during the procedure. Supplemental calcium was administered by infusion to maintain ionized calcium >9 mmol/L. All patients were given 4 g of piperacillin before skin incision and every 8 h for 48 h. For immunosuppression, the administration of prednisolone and azathioprine was begun with the induction of anesthesia (respectively, 5 and 1 mg/kg). In the postoperative period, cyclosporine A was administered intravenously and the dose augmented from 1 to 6 mg/kg.

Monitored variables included mean arterial pressure (MAP [mm Hg]) through a radial artery catheter; thermodilution cardiac index (CI [$L \cdot min^{-1} \cdot m^{-2}$]) through a balloon-tipped pulmonary artery catheter; superior vena cava pressure (mm Hg); inferior vena cava pressure (IVCP [mm Hg]), measured through a 6F 30-cm catheter inserted via the left femoral vein; and renal perfusion pressure (RPP [mm Hg]), calculated as follows: RPP = MAP − IVCP. Intraoperative measurements were made at three times: 2 h after induction of anesthesia (dissection phase), 10 min before the end of the anhepatic phase (anhepatic phase), and 2 h after inferior vena cava (IVC) unclamping (postreperfusion phase). Urinary output (UO [$mL \cdot kg^{-1} \cdot h^{-1}$]) was recorded during each phase of the surgical procedure. The SCr values were measured just before OLT and on the third day after surgery. The administration of blood products was measured at each stage of the operation.

At the completion of the dissection phase, all patients underwent a 5-min test period to determine their hemodynamic response to the clamping of the suprahepatic and infrahepatic vena cava and portal vein. During the next 5 min, the patients were observed for hemodynamic instability, and additional volume was administered to treat hypotension. In patients in whom the test period resulted in a decrease in MAP of >30% or a decrease in CI of >50%, or both, venovenous bypass was utilized to provide hemodynamic support during the anhepatic period. In these patients (n = 17, BP group), the clamps were removed and the bypass cannulas placed in the portal and femoral veins. Blood was pumped from the portal and femoral veins through an extracorporeal circuit without the use of heparin and returned to the left internal jugular vein or the left axillary vein. We used a nonocclusive pump (RP 06 GN, Rhône-Poulenc, Paris, France), the adjustable output of which may in theory be modulated from 0 to 7 L/min. The pump was connected at the end of the dissection phase and disconnected a few minutes after IVC unclamping. Pump flow was continually maximized by the anesthetist, but the blood flow could not be precisely determined, because there was no Doppler flowmeter on the bypass circuit. In the remaining patients (n = 21, NBP group), venovenous bypass was not utilized, and hemodynamic support was maintained by volume administration.

During the surgical procedure, furosemide was administered if the mean pulmonary arterial pressure increased above 35 mm Hg or if oliguria occurred (<1 $mL \cdot kg^{-1} \cdot h^{-1}$ UO). No patient received dopamine during this study.

Statistical analysis was performed with repeated measures analysis of variance followed by appropriate post hoc tests, two-tailed Student's t-test, or Mann-Whitney U-test for normally distributed variables and χ^2-analysis for nonparametric variables. Yates' correction was used when necessary; $P < 0.05$ was considered statistically significant.

Results

Demographic data and diagnosis are reported in Table 1. Age, weight, and preoperative SCr values were similar in the two groups of patients.

Hemodynamic results are listed in Table 2. During the dissection phase, hemodynamic profiles were similar in both the BP group and the NBP group. Likewise, there was no difference in RPP between the two groups. During the anhepatic phase, CI decreased in both groups; superior vena cava pressure decreased in the NBP group when it remained unchanged in the BP group; and IVCP increased with and without bypass. This increase of IVCP was observed throughout the period of IVC clamping and was much greater in the NBP group. Because MAP rapidly returned to preanhepatic values in both groups after IVC clamping, RPP was significantly

Table 1. Clinical Characteristics of 38 Patients Undergoing Orthotopic Liver Transplantation (OLT)

	BP group (n = 17)	NBP group (n = 21)
Gender (M/F)	9/8	19/2
Diagnosis		
Sclerosing cholangitis	1	3
Cirrhosis	13	18
Age (yr)	44 ± 10	41 ± 11
Wt (kg)	65 ± 12	63 ± 10
Preoperative SCr concentration (μmol/L)	72 ± 18	73 ± 13

BP, patients undergoing OLT with bypass; NBP, patients undergoing OLT without bypass; M, male; F, female; wt, weight; SCr, serum creatinine. Mean ± SD.

reduced during all of the anhepatic stage in the NBP group but was not significantly modified in the BP group. During the postreperfusion phase, IVCP and RPP returned to preanhepatic values in both groups.

The UO during the three stages of liver transplantation in the two groups is reported in Table 3. During the dissection phase, UO was similar in both groups. During the clamping period, UO was not modified in the BP group, whereas it significantly decreased in the NBP group. However, during the postreperfusion phase, UO was greater in both groups compared with UO during the dissection phase. No correlations were found between UO and RPP, UO and MAP, or UO and IVCP in either group during any phase of the surgery. It is of note that 11 of 17 patients in the BP group and 14 of 21 patients in the NBP group received furosemide once or many times during at least one phase of the procedure. The number of patients who received furosemide was similar in both groups. Compared with preoperative values, SCr was increased in both groups on the third postoperative day, but this increase was significant only in the BP group. There were no significant differences in SCr between the two groups on the third postoperative day (NBP group 126 ± 95 mmol/L; BP group 107 ± 49 mmol/L), and no patient needed dialysis therapy in the postoperative period. Nine patients in the NBP group and four in the BP group developed a 50% or greater increase in postoperative SCr compared with pretransplant values; however, this difference was not significant.

The duration of the dissection, anhepatic, and postreperfusion phases was similar in the two groups (Table 4). There was no difference between the two groups concerning the total amount of blood products administered during the entire procedure (data not shown). The transfusion of packed red blood cells was similar in both groups during each phase of the surgery. The quantities of fresh-frozen plasma received by the patients were similar during the dissection and postreperfusion phases but were significantly less in the BP group during the anhepatic stage (Table 4).

Discussion

In patients who did not receive bypass support, despite the changes in UO and RPP during the anhepatic phase, no decrement in early renal function could be found compared with the other group in whom UO and RPP had been maintained with the use of bypass.

In our institution, bypass is not used routinely during the anhepatic phase of OLT. We use it selectively in case of fulminant hepatic failure, preoperative renal failure, or when a 5-min trial of venous cross-clamping is not hemodynamically tolerated. The risks of venous bypass should not be neglected. Intraoperative deaths attributable to emboli of air or thrombus have been reported during the bypass period (9). Although embolism remains the most serious hazard of bypass, other problems may occur: longer operative and anhepatic times are inevitable; warm ischemia and the associated risk of graft primary nonfunction may be increased; body temperature may be difficult to maintain (10,11); and local complications, including hematoma, lymphocele, and infection, may also be troublesome. These risks explain why we did not find it ethical to perform a study in which patients who were tolerating the trial of venous cross-clamping well would have been randomly assigned to a group with bypass or to a group without bypass. As such, the two groups are potentially different in their degree of retroperitoneal collateralization and may have received additional collateral flow to their kidneys. Moreover, the two groups may differ in their endogenous reflex responses to acute hypovolemia. Given these restraints and the small number of patients in each group, we cannot definitely conclude that the use of bypass would not improve renal function in the population of patients that did not receive bypass. However, although not randomized, this study is the first that aims at comparing the evolution of renal hemodynamics and renal function during OLT with and without bypass. Of note in our study, we had no accident caused by the use of bypass.

During the anhepatic stage, hemodynamic profiles indicated a lower rate of venous return in both groups, with a higher IVCP and a lower CI, as previously described with and without bypass (6,7,10,12). Thus, even if bypass reduces the hemodynamic changes associated with occlusion of the IVC and portal vein during the anhepatic phase of the transplant procedure, it is likely that bypass was not

totally effective in maintaining venous return. Superior vena cava pressure was decreased only in the NBP group when it was not significantly modified in the BP group; however, MAP and CI variations were similar in both groups between the dissection and anhepatic phases.

As expected, after IVC unclamping, IVCP decreased dramatically in the NBP group and returned to its preanhapatic value. This result is in contradiction with the conclusions of Estrin et al. (7) who found that IVCP was still significantly higher after IVC unclamping than before clamping in a group of 26 adult liver recipients not supported with bypass during the anhepatic phase and in whom MAP was maintained during the anhepatic stage by the use of increasing intravascular blood volume (via a rapid infusion system) and inotropic drugs.

The occurrence of renal failure during or after OLT is a serious event. Thus, in a retrospective study that involved 46 transplant patients, Kirby et al. (1) reported 80% mortality among patients suffering from postoperative renal failure. Although pretransplant renal impairment is not associated with an increased risk of death, a postoperative peak SCr >3 mg/dL (265 μmol/L) would carry a significant risk of death (2). In our study, SCr did not reach this value in any patient. Moreover, the etiology of acute renal failure is a major determinant of patient survival. The most common and serious cause of renal failure after OLT is acute tubular necrosis related to prolonged ischemia associated with sepsis (2,13). Hemorrhage, hypotension from massive blood loss complicated by the vascular instability provides a well-recognized clinical environment in which ischemic renal damage often occurs (14). Renal function is therefore threatened at each phase of OLT. During the anhepatic phase, renal perfusion is notably impaired; indeed, interruption of the IVC produces venous hypertension upstream and venous congestion of infrahepatic structures. Several published studies dealing with the incidence of acute renal failure in adult OLT may be found (2–4). In these, the frequency of acute renal failure varies from 21% (4) to 94.2% (2). This variability in the frequency of renal failure is due at least in part to the criteria chosen to define it. Thus, for Iwatsuki et al. (4), renal failure was defined as the development of a blood urea nitrogen of 50 mg/dL (8 mmol/L) or an SCr of 2 mg/dL (177 μmol/L). For McCauley et al. (2), renal failure was defined as a ≥50% increase in postoperative SCr compared with pretransplant values. Among our patients, 9 of 21 in the NBP group and 4 of 17 in the BP group presented a ≥50% increase in postoperative SCr compared with preoperative values; however, this difference was not significant.

The systematic use of bypass has been suggested to limit the incidence of renal failure after OLT. Nevertheless, it is essential to note that the use of bypass during the anhepatic phase of adult OLT remains controversial. Some transplant centers use bypass routinely (8,10); others never use bypass (7). Shaw et al. (8) found a lower peroperative blood loss

[a] $P < 0.05$ vs NBP.

and a lower incidence of postoperative renal failure when bypass was used. This they deduced to be due to bypass decompression of the portal hypertension present in the majority of the transplant patients. For other authors, the bypass would not be beneficial in terms of decreasing blood loss during the procedure (15,16). We agree with the latter opinion, because in our study there was no difference between the two groups concerning the total amount of blood products administered during the procedure. The transfusion of packed red blood cells was similar at each phase of the surgery, and the only difference we found concerned the amount of fresh-frozen plasma administered during the anhepatic stage. J. P. Massini et al., in a retrospective study of 33 OLT operations in adults with preoperative SCr <150 μmol/L, found no differences in renal function whether bypass was used or not (communication at the third meeting of the Liver Intensive Care Group of Europe, Brussels, March 1990). In this study, postoperative renal dysfunction was mainly associated with intraoperative difficulties (duration of the anhepatic phase) and blood loss. Finally, we agree with others (15) that bypass is not necessary as a routine during OLT, but it may have a role in patients with compromised cardiac reserve, because it provides better hemodynamic conditions during the anhepatic period of OLT.

Estrin et al. (7) suggested monitoring RPP to maintain it >50 mm Hg during the entire operative period. This 50-mm Hg value might correspond to the lower limit of RPP under which autoregulation of renal blood flow no longer exists. Maintaining RPP >50 mm Hg should allow the renal effect that could be due to the vascular cross-clamping during the anhepatic phase to be limited. In our study, we have recorded RPP values without trying to influence them. During the anhepatic stage, RPP was not modified in the BP group and remained >50 mm Hg in all patients. In the NBP group, during the same period, RPP was significantly reduced and was <50 mm Hg in 8 of 21 patients. Yet, diuresis after IVC unclamping and SCr on the third postoperative day were similar in both groups. Moreover, in the NBP group there was no significant difference in postoperative renal function whether RPP was above or under 50 mm Hg. Thus, RPP monitoring to maintain it above 50 mm Hg during the anhepatic phase may not be needed to preserve renal function. We have now abandoned IVC catheterization for measuring IVCP uniquely. This procedure is not without complications, and during our study one case of a femoral arteriovenous fistula occurred, certainly attributable to the catheter, that required surgery.

In conclusion, this study suggests that in patients without preoperative renal failure and who tolerate the trial of clamping well, the nonutilization of bypass did not result in increased peroperative blood loss or decreased early postoperative renal function. Even if diuresis during the anhepatic phase was more with bypass, postreperfusion UO and SCr values on the third postoperative day were similar, independent of bypass use. At the end of this study the question remains unanswered as to whether patients who did not require bypass after a test period of cava and portal clamping benefit in any way by the routine use of bypass.

We gratefully acknowledge M. C. Gillon, MD, H. Soilleux, MD, L. Barthe, MD, A. Descorps-Declere, MD, and A. Mirand, MD, for their participation in this study.

Buccal Pulse Oximeter Is More Accurate Than Finger Pulse Oximeter in Measuring Oxygen Saturation

Richard J. O'Leary, Jr., BA, Mark Landon, MD, and Jonathan L. Benumof, MD

Department of Anesthesiology, University of California—San Diego, School of Medicine, San Diego, California

Although there have been several anecdotal reports of the use of buccal pulse oximeter monitoring (Spo_2) when digital Spo_2 monitoring cannot be used, there have been no objective evaluations of the accuracy of buccal Spo_2 monitoring. The purpose of this study was to systematically compare buccal Spo_2 monitoring to both digital Spo_2 and arterial O_2 saturation monitoring (Sao_2) in both generally anesthetized patients in the operating room ($n = 31$) and critically ill patients in the intensive care unit ($n = 23$). Buccal Spo_2 probes were prepared by taping a malleable metal bar securely over the back of a Nellcor Oxisensor D-25 probe and bending the metal bar and buccal probe firmly around the corner of the patient's mouth. All buccal and finger Spo_2 and Sao_2 measurements were made simultaneously during hemodynamic stability. We found that buccal Spo_2 was higher than finger Spo_2 and agreed more closely with Sao_2 for both patient groups (98.1% ± 2.6%, 96.8% ± 3.5%, 98.5% ± 2.5%, respectively [mean ± SD]). The operating room patients had higher buccal and finger Spo_2 and Sao_2 (99.3% ± 1.5%, 98.9% ± 1.4%, 99.5% ± 0.7%, respectively) than the intensive care unit patients (96.4% ± 2.9%, 94.1% ± 3.5%, 96.6% ± 3.5%, respectively). Although buccal Spo_2 monitoring has several disadvantages (i.e., the probe requires preparation, can be more difficult to place, may be less readily accepted in awake patients, and is often mechanically dislodged during airway maneuvers), we conclude that buccal Spo_2 monitoring is a more than adequate oximetry alternative when digital Spo_2 monitoring is not an option (digits are unavailable or available digits are mechanically interfered with).

(Anesth Analg 1992;75:495–8)

The use of pulse oximeter monitoring (Spo_2) is now a standard of care in anesthesiology (1). However, the reliability of pulse oximetry probes when applied to the fingers or toes may be compromised in certain patients, such as those who become hypothermic, have decreased cardiac output, have increased systemic vascular resistance, and those who have their extremities or digits mechanically interfered with or who are shivering or moving the monitored digit. As a result, other sites less subject to mechanical interference or a pathophysiologic decrease in pulse amplitude, or both, have been sought, thereby allowing Spo_2 monitoring over a wider variety of surgical and physiologic conditions.

Jobes and Nicolson (2) modified a standard pulse oximeter probe so that it could be attached to the patient's tongue. The hypothesis was that the circulation of the tongue was perhaps more central and therefore better perfused, allowing for more accurate monitoring despite the previously mentioned pathophysiologic factors. In three patients with congenital heart defects who were undergoing cardiac surgery, the tongue sensor functioned well continuously, whereas the peripheral digital sensor functioned only intermittently (one case) or not at all (two cases).

Gunter (3), noting difficulty in keeping the sensor applied to the tongue, modified the probe slightly by attaching a stiffer metal strip to the back of it. He then placed the new metal-backed probe across the lip at the corner of the mouth (i.e., a "buccal" or "cheek" Spo_2 monitor). He noted that the buccal site was always available, very easy to apply, and stayed in place, and without offering any data he concluded that the monitor was reliable even in the presence of arterial vasoconstriction or low cardiac output. Similarly, Sosis and Coleman (4), without reporting any data, monitored buccal Spo_2 by means of an unmodified Ohmeda ear probe. Ezri and colleagues (5) have recently used a probe across the nasal septum with good results.

Although the reports published thus far seem promising (2–4), there have been no formal comparisons of buccal Spo_2 monitoring with digital Spo_2 or arterial oxygen saturation (Sao_2 monitoring). The

purpose of this study was to systematically compare buccal Spo$_2$ monitoring to both digital Spo$_2$ and Sao$_2$ monitoring in both generally anesthetized patients in the operating room (OR) and critically ill patients in the intensive care unit (ICU).

Methods

A total of 54 informed, consenting nonsmoking patients were studied: 31 underwent general anesthesia in the OR (OR group), and 23 were monitored in the ICU (ICU group) (Table 1). Patients with indwelling arterial lines (n = 33 [10 in the ICU group, 23 in the OR group]) received simultaneous arterial blood gas analysis (Sao$_2$) with the use of a CO-oximeter 282 (Instrumentation Laboratories, Lexington, Mass.). The buccal mucosa probes were prepared in a manner similar to that described previously by Gunter (3) by taping a malleable metal bar securely over the back of a Nellcor Oxisensor D-25 probe (Nellcor Inc., Hayward, Calif.). Two to three centimeters of the distal tip of the probe were cut off to leave a rounded, tapered end that was easier and less traumatic to insert into the patient's mouth.

All OR-group patients had finger pulse oximeters placed before induction of anesthesia. As soon as it was convenient after induction of anesthesia (generally within 5–10 min), the buccal mucosa probe was placed in the corner of the mouth. Each probe was connected to its own Nellcor model N-100 pulse oximeter. Both machines had been previously checked to ensure that they gave the same reading when attached to the same probe to guarantee that any differences displayed were not due to differences in the sensitivities of each machine. Buccal and finger Spo$_2$ and Sao$_2$ measurements were made simultaneously during a hemodynamically stable postinduction period of anesthesia.

Buccal and finger Spo$_2$ and Sao$_2$ were measured in the mechanically ventilated ICU-group patients during a hemodynamically stable period of time. The probe was placed in the patient's mouth for a few minutes and the readings allowed to stabilize before blood was drawn for blood gas analysis. Once the values were recorded, the probe was usually removed from the ICU-group patient's mouth (some buccal probes were left in for continued monitoring by request of the ICU nurses). One set of observations was obtained in each patient for the purposes of the study.

Table 2. Oxygen Saturation Values in All Patient Groups

Oxygen saturation measurement	Patient group OR	ICU	Total
Sao$_2$	99.5 ± 0.7 (96.9–100)	96.6 ± 3.5 (90.1–100)	98.5 ± 2.5 (90.1–100)
Buccal Spo$_2$	99.3 ± 1.5 (95.0–100)	96.4 ± 2.9 (90.0–100)	98.1 ± 2.6 (90.0–100)
(Pts w/Sao$_2$ reading)	(99.1 ± 1.6)	(97.2 ± 2.5)	(98.4 ± 2.1)
Finger Spo$_2$	98.9 ± 1.4 (95.0–100)	94.1 ± 3.5 (88.0–100)	96.8 ± 3.5 (88.0–100)
(Pts w/Sao$_2$ reading)	(99.0 ± 1.5)	(95.4 ± 3.4)	(97.7 ± 3.0)

OR, operating room; ICU, intensive care unit; Sao$_2$, arterial oxygen saturation; Spo$_2$, pulse oximetry; (Pts w/Sao$_2$ reading), (mean ± SD) buccal and finger Spo$_2$ values for just the patients who had simultaneous Sao$_2$ determinations.

The levels of measurement agreement between finger and buccal sensors as well as between Sao$_2$ and each type of probe were calculated with the method outlined by Bland and Altman (6). The mean difference represents the average difference between each of the data points. Standard error of the mean difference (SEM) was calculated by dividing the standard deviation by $n^{1/2}$, where n = sample size. The limit of agreement represents the mean difference ± 2s (s = standard deviation of the differences). The standard error of the limits of agreement was calculated using the formula $(3s^2/n)^{1/2}$ (6).

Results

Table 2 summarizes the oxygen saturation data in all patient groups. In general, we found that buccal Spo$_2$ was higher on average than finger Spo$_2$ and agreed more closely with Sao$_2$ for all patient groups.

Table 3, which summarizes our statistical analysis, indicates that the buccal Spo$_2$ agreed very closely with Sao$_2$, as shown by the very small mean difference of −0.1% between the two values for all patients, whereas finger Spo$_2$ did not agree nearly as closely with Sao$_2$, with a mean difference of −0.8%. The standard error of limits is similarly smaller in the case of buccal Spo$_2$ versus Sao$_2$ (0.4) compared with finger Spo$_2$ versus Sao$_2$ (0.5). Buccal Spo$_2$ was always higher than finger Spo$_2$ (positive mean difference of 1.2%). We observed the greatest variation between buccal Spo$_2$ and finger Spo$_2$ in patients who had edema in the monitored limb; in patients with severe

Table 3. Summary of Between-Method Statistical Comparisons for the Oxygen Saturation (Spo$_2$) Measurements[a]

Oxygen saturation comparison		Statistical comparison					
Measurement	Patient group	*n*	Mean difference (%)	s	SEM	Limits of agreement	Standard error of limit
Buccal Spo$_2$ vs finger Spo$_2$	OR	31	0.3	1.56	0.3	3.4 to −2.8	0.5
	ICU	23	2.3	2.24	0.5	6.8 to −2.1	0.8
	Total	54	1.2	2.13	0.2	5.4 to −3.1	0.3
Buccal Spo$_2$ vs Sao$_2$	OR	23	−0.5	1.21	0.3	2.0 to −2.9	0.4
	ICU	10	0.6	1.59	0.5	3.8 to −2.5	0.9
	Total	33	−0.1	1.41	0.3	2.7 to −2.9	0.4
Finger Spo$_2$ vs Sao$_2$	OR	23	−0.5	1.15	0.2	1.7 to −2.3	0.4
	ICU	10	−1.2	2.12	0.7	3.0 to −5.4	1.2
	Total	33	−0.8	1.57	0.3	2.4 to 3.9	0.5

[a]Statistical comparisons for buccal and finger Spo$_2$ vs Sao$_2$ are only for the patients who had simultaneous paired determination.

edema, the difference was as much as a positive 5%–6%. The reader may note that in Table 3 (comparisons of the two probes with Sao$_2$), the mean difference represents only those patients who had Sao$_2$ analysis. In Table 2, the average readings of these patients as well as of the entire patient population are given.

On average, the ICU-group patients had lower oxygen saturation than did the OR-group patients (Table 2). Both buccal Spo$_2$ and finger Spo$_2$ were less accurate relative to Sao$_2$ in the ICU-group patients compared with the OR-group patients, as evidenced by the larger mean difference and limits of agreement for the ICU versus the OR group (Table 3). However, the buccal Spo$_2$ is also statistically closer to Sao$_2$ in the ICU group than the finger Spo$_2$, as demonstrated by the buccal Spo$_2$ versus Sao$_2$ mean difference of 0.6% compared with the finger Spo$_2$ versus Sao$_2$ mean difference of −1.2%. Similarly, the buccal Spo$_2$ versus Sao$_2$ mean difference for the ICU group is 0.625 (limit of agreement of 3.8 to −2.55), whereas the finger Spo$_2$ versus Sao$_2$ mean difference is −1.2 (limits of agreement of 3.04 to −5.44) for the ICU group.

Discussion

Our main objective in performing this clinical study was to determine whether buccal Spo$_2$ monitoring was at least as accurate as finger Spo$_2$ monitoring relative to simultaneous Sao$_2$ monitoring. We found that buccal Spo$_2$ was more accurate than finger Spo$_2$ relative to measured Sao$_2$. We did not correct measured Sao$_2$ with levels of methemoglobin and carboxyhemoglobin, because we were looking for a relative standard to measure each of the two probes against. Although it is conceivable that the levels of methemoglobin and carboxyhemoglobin could account for some of the difference between Sao$_2$ and Spo$_2$ measured at the buccal and digital sites, the difference is a constant because all readings were made simultaneously. In the absence of smoking (minimal carboxyhemoglobin and methemoglobin levels), simultaneous Sao$_2$ is a relevant control saturation.

We chose not to analyze our data with correlation coefficients that were generated by linear regression based on the arguments presented by Bland and Altman (6); the argument includes the fact that there will be perfect agreement only if all of the data points lie along a line of equality, but there can be perfect correlation if the points lie along any straight line. This point is demonstrated by Ezri et al. (5) who found nearly identical correlation coefficients between nasal septum Spo$_2$ and Sao$_2$ (0.968) and finger Spo$_2$ and Sao$_2$ (0.970), even though there were very different mean differences (0.15 vs 2.27, respectively) and limits of agreement (−0.1 to 0.4 vs 2.0 to 2.6, respectively) between the two measures of oxygen saturation. We instead compared the values produced by two different measuring devices by a direct between-method differences analysis. The limits of agreement are only estimates of the value that apply to the whole population. The standard error is used to determine how precise the estimates are; the smaller the standard error, the more accurate the estimate is for the population (6).

We found that buccal Spo$_2$ was always higher than finger Spo$_2$ and agreed more closely with Sao$_2$, even in conditions where differences between measurement methods were increased (i.e., the more hypoxemic ICU group). It may be that buccal pulsations are stronger under a wider variety of clinical conditions and result in more accurate oximeter saturation readings. Coupled with its high incidence of availability, the accuracy of the buccal Spo$_2$ makes it an attractive alternative to finger Spo$_2$ monitoring.

If the magnitude of the Spo_2 limits of agreement is clinically unimportant, the devices would be interchangeable. In this study we found that buccal Spo_2 versus Sao_2 had limits of agreement of 2.75 to −2.88. The finger Spo_2 versus Sao_2 had limits of agreement of 2.35 to −3.92. It could be argued that these levels of difference are clinically irrelevant, thereby making either device a satisfactory method of monitoring the patient's oxygenation. Although the buccal site does not represent a marked improvement, it is slightly more accurate by our calculations. An anesthesiologist can therefore be assured that the readings observed with a buccal probe are an accurate indication of the patient's oxygen saturation status.

We encountered four major technical difficulties in applying buccal Spo_2 monitoring. First, the buccal probe is less well accepted in awake patients compared with the finger probe. Second, the buccal probe can be displaced or interfered with during ventilation of the patient through an anesthesia mask and during laryngoscopy. Third, given the usual (normal) unrestricted exposure to the extremity and the corner of the mouth, it is initially somewhat more time consuming to prepare and place a buccal probe compared with a finger probe. Fourth, in the lateral decubitus position, saliva may accumulate over time, making it difficult to maintain probe position on the dependent corner of the mouth. This problem can be solved by placing the probe on the upper corner of the mouth or by administering an anticholinergic agent to reduce saliva production.

In conclusion, the use of buccal Spo_2 monitoring makes sense for several reasons. First, the corner of the mouth is usually readily accessible to the anesthesiologist, whereas the digits are often remote or made inaccessible by the surgical drapes or the patient's position. Second, in patients who have burns or other serious injury to their hands and feet, the buccal mucosa may be the only available site for pulse oximetry monitoring. Third, the buccal Spo_2 values are accurate (compared with simultaneous Sao_2). Indeed, it appears that the circulation to the buccal mucosa is less subject to peripheral vasoconstriction and decreased pulse amplitude than are the peripheral sites used for pulse oximetry, such as the fingers and toes. Therefore, the anesthesiologist using buccal Spo_2 monitoring, either from convenience or necessity, can be confident that the readings are at least as accurate as the commonly used finger probe in determining the patient's level of oxygen saturation.

Recognition Accuracy of Current Operating Room Alarm

Robert G. Loeb, MD, Brian R. Jones, MD, Rebecca A. Leonard, PhD,
and Kendra Behrman, RN

Departments of Anesthesiology and Otolaryngology, University of California—Davis, Medical Center,
Sacramento, California

This prospective study was performed to determine whether anesthesia clinicians (i.e., both anesthesiologists and nurse anesthetists) can identify operating room alarms by their distinctive sounds and to identify factors related to alarm recognition accuracy. Nineteen alarms from 15 commonly used devices were recorded. These sounds were played, in a quiet room, to 44 anesthesia clinicians. The clinicians were asked to choose from a list the device that produced the alarm. After this recognition test, the clinicians rated the importance of each alarm and the frequency with which they heard it in the clinical situation. Clinicians correctly identified the alar source 34% of the time. The recognition rate wa higher for alarms rated as heard more frequently however, alarms that were rated as more importan were *less* likely to be correctly identified. Complexit of the sound did not influence accuracy of recognition. Most errors were attributed to similarities i sound or function, or both, among alarms. We conclude that anesthetists cannot reliably identify current operating room alarms by their distinctiv sounds.

(Anesth Analg 1992;75:499–505

Modern operating rooms are filled with devices that generate audible alarms intended to alert the clinician to potentially hazardous conditions. It is therefore important that the clinician be able to quickly identify any alarm, because the inability to do so can delay or prevent the appropriate corrective action (1).

The three criteria for determining the effectiveness of audible alarms are audibility, attention demand, and recognition (2). Audibility refers to whether a sound can be heard in the presence of typical background noise. Attention demand is a measure of whether an unexpected alarm will be perceived. Recognition implies that the sound will be interpreted as an alarm and that its meaning will be understood.

Noise-level readings taken during typical operations have established the fact that the operating room is indeed a noisy environment, comparable to that of a freeway (3,4). Even so, audible alarm signals that can be reliably detected above operating room noise levels have been identified (5). Stanford et al. (5) concluded that signals with spectral richness, frequency modulation, and temporal patte could be reliably detected amid operating equipment noises in a laboratory setting.

There are anecdotal reports of difficulty in i fying the source of an alarm in the clinical en ment (6,7). A presumed reason is that many a have similar sounds; yet, of 852 Canadian an tists responding to a survey, half (422) indicate the distinctiveness of the alarm sound was useful in determining its source than was eith direction of the sound source or a visual indicat The aim of our study was to measure anes clinicians' ability to identify the source of fa alarms by sound characteristics alone. We also i tigated the factors that influence alarm recogni

Methods

Nineteen alarm sounds from 15 devices in our ating rooms were digitally recorded at 22 Hz 8-bit resolution. The volume of each alarm wa measured with a precision sound-level meter (2209, Brüel and Kjaer Instrumentation Co., Ma ough, Mass.) (A scale). Each volume measure was performed from the head of the operating table and at a height of 4 ft, with the device typical location and set at its default volume The volume of each recorded alarm, played th headphones, was then adjusted to that of the or

alarm by means of the sound-level meter and a commercial software program (SoundEdit 1.0, Farallon Computing, Berkeley, Calif.). The complexity of each alarm sound was rated by an audiologist who was unfamiliar with the operating room. She classified each as continuous tone, intermittent tones separated by periods of silence, or multitone.

Our institutional review board granted approval, and all subjects consented to the study. Twenty-three anesthesia residents, 12 anesthesia attending physicians, and nine certified registered nurse anesthetists (CRNA) participated. Each of the subjects routinely used all of the devices from which the alarms were recorded.

Each subject was tested while seated in a quiet room. The subject's hearing was screened at 1000, 2000, 3000, and 5000 Hz, and deficits >30 dB were noted. After the hearing test, the subject heard the recorded alarm sounds through calibrated headphones. The alarms were presented in random order, and each was presented twice during the session. The subject was asked to select from a list the device that generated the alarm sound. The list contained one entry for each of the 15 devices and an entry named "Don't know." Each entry listed the type of device, the manufacturer, and a short description of the device's appearance. Subjects received the following written instructions:

> Each alarm will sound for 17 seconds and will be followed by 10 seconds of silence. You should verbally identify the monitor which generates the alarm as soon as you can during the 27 seconds after the alarm begins to sound. If you have not responded after the 27 seconds have elapsed, you will be asked to either identify the monitor or indicate that you "don't know".

After the alarm recognition test, each subject was given a list of the 19 alarm sounds and was asked to indicate for each (a) how important the alarm is in clinical practice (critical, important, or advisory); and (b) how frequently, in his or her experience, the alarm occurred (frequently, infrequently, or rarely). Two demographic items were collected for each subject: (a) clinical training (resident, faculty, or CRNA); and (b) clinical experience (number of years since beginning anesthesia training).

Data are expressed as frequencies of correct recognitions. Comparisons between groups of alarm importance and frequency of alarm occurrence were by χ^2 analysis. The correlation between each clinician's rating of alarm importance and frequency of alarm occurrence was analyzed with Spearman rank correlation. Least-squares regression was used to determine the effects of clinical experience and alarm volume on recognition rate. Tests were performed with Data Desk version 3.0 (Odesta Corp., Northbrook, Ill.). A value of $P < 0.05$ was considered significant.

Results

Forty-four anesthesia clinicians heard each of 19 alarms twice, providing a total of 1672 responses. Table 1 presents the frequencies of responses for each alarm sound. The correct responses are outlined on the main diagonal. The alarm sounds were correctly identified 571 times (34%) and incorrectly identified 843 times (50%); clinicians admitted to not knowing the correct answer 258 times (16%).

The clinician with the best performance, a new resident, identified 26 alarms correctly (68%); the worst performance, by a clinician with 26 years' experience, was three correct (8%). There was no correlation between a subject's clinical experience and his or her ability to correctly identify alarms (Figure 1). Hearing deficits were detected in six subjects. The scores of the clinicians with hearing deficits were not different from those with normal hearing.

On the questionnaire, clinicians judged the tested alarms as critical 37% of the time, important 34% of the time, and advisory 29% of the time. When clinicians rated an alarm as more important, it was less likely that they would correctly identify it (Figure 2). Alarms were rated as being frequently, infrequently, and rarely heard 30%, 30%, and 41% of the time, respectively. The more frequently clinicians believed that they heard an alarm, the more likely it was that they would identify it (Figure 3). For each clinician, there was a negative correlation between how important he or she thought the alarm was and how frequently he or she thought that it was heard. The alarms believed to be less important were judged to be heard more frequently.

The alarm with the highest recognition rate (Fisher & Paykel humidifier) was correctly identified 92% of the time, whereas that with the lowest recognition rate (Ohmeda 7000 Ventilator power failure) was correctly identified only 1% of the time. Six of the alarms were continuous tones, five were intermittent tones separated by periods of silence, and eight were multitone. Sound complexity did not affect recognition rate; however, there was a positive correlation between alarm volume and recognition rate ($P < 0.01$) (Figure 4).

Table 1 presents the frequencies of responses for each alarm sound. The correct responses are outlined on the main diagonal. Entries outside the main diagonal and the "Don't know" column are mismatches; these may have occurred owing to confusion or chance. Mismatches due to random chance would result in a cell frequency of

[88 − (No. of "Don't know" responses)] ÷ 15

for each row. Cell frequencies that exceed this threshold indicate a relevant confusion (9). Interpreted in this way, 571 responses were correct (34%), 573 were relevant confusions (34%), 258 were "Don't know" (16%), and 270 were random mismatches (16%).

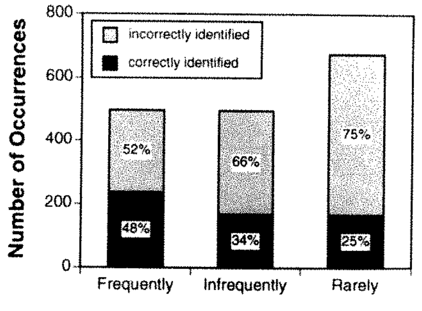

Figure 3. Number of correctly and incorrectly identified alarm sounds versus how frequently the clinician hears the alarm in clinical practice. There is a significant difference between groups ($P < 0.0001$).

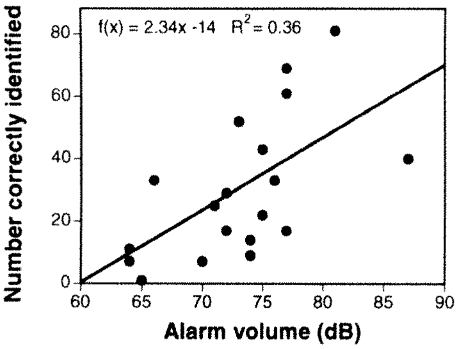

Figure 4. The number of times an alarm was correctly identified versus the alarm volume. Each alarm was presented 88 times, twice each to 44 subjects. The linear regression line is significant at $P < 0.01$.

Discussion

The data indicate that anesthesia clinicians cannot determine the source of current commercial operating room alarms solely by sound characteristics. This contradicts the subjective impression (8). The study does not imply that alarms cannot be identified quickly in the clinical setting. During clinical use, identification may be facilitated by visual indicators on the monitor, the direction from which the sound is produced, and interpretation of the clinical scenario at the time of the event.

Alarm recognition in the operating room is hampered when each device has a proprietary alarm sound. This is due to a number of factors. First, numerous sounds must be recognized. We identified 19 audible alarms in the operating rooms at our institution. Second, alarms may occur simultaneously. Third, the user may rarely use a particular device and thus infrequently hear a particular alarm. Experiments by Patterson and Milroy (10) indicate that subjects can readily learn to recognize four to six audible alarms, and 1 wk after learning 10 alarms, subjects can reliably recognize only six. This is consistent with other studies that demonstrate the limitations of humans in differentiating among multiple stimuli (11). It suggests that the number of alarm sounds should be reduced to a maximum of six. The number of sounds can be decreased in two ways: standardization of sounds and limitation of alarms. Standardized alarms could reduce the total number of sounds and would ensure that unfamiliar equipment had familiar alarms. Limiting the use of audible alarms would reduce the total number of sounds and the chance of simultaneous alarms. Eventually, integrated monitoring systems with centralized alarms would be ideal, but in the interim, the situation could be improved by standardizing audible alarms and limiting their use.

It is intuitive that the most important alarms should have sounds that are most easily identified by anesthesiologists; however, we found an inverse relationship between alarm importance and recognizability. For example, the Fisher & Paykel humidifier alarm had a low importance rating but was very well recognized. This alarm is loud, continuous, and has a complex sound pattern. These features may elicit a strong affective response in the anesthetist that may increase recognition. A related study by Finley and Cohen (12) found no correlation between the perceived urgency of commercial operating room alarm sounds and the urgency of the clinical situation. Thus, there is accumulating evidence that current commercial auditory alarms are poorly correlated to the situations of which they are warning.

Although our study demonstrates a problem with the current unstructured approach to alarms, it provides little data to guide manufacturers in developing more recognizable alarms. There was a positive correlation between alarm volume and recognition rate; however, we do not recommend that alarm volumes be increased indiscriminately. An anesthesiologist's initial response might be to silence a louder alarm rather than address the clinical problem that caused it. Also, louder alarms would be more disruptive to the rest of the operating room team. We presumed that the more complex alarm sounds would be better recognized, but our data do not support this conclusion. Additional research is needed to develop alarm sounds that are recognizable and detectable but not disruptive. The more urgent and recognizable sounds should be reserved for the more important alarms, and before general use, the sounds should be evaluated in operating rooms to determine their effect on personnel performance.

We looked for patterns of recognition errors in our data to understand the processes involved in recognizing alarm sounds. This method has been used previously to investigate factors that affect other

[a] Even though it is not an alarm, the "buzzing" sound of electrocautery was included in this category. See text for explanation.

recognition tasks (9). We were most interested in understanding the relevant confusions, because these signify systematic errors in the interpretation of the alarm sounds. Retrospective review of the data suggested that many mismatches resulted from two underlying causes: (a) sound confusion and (b) function confusion. The first, sound confusion, was a mismatch between alarms with similar sound qualities. We retrospectively classified the alarms by similarity of sound into seven categories (Table 2). Table 1 is grouped by sound categories to highlight the areas of potential confusion. An example of sound confusion is the 14 responses of "Dinamap" to the Ohmeda Modulus II power failure alarm. The Modulus and Dinamap alarms sound similar; both are complex sounds with a burst of patterned tones separated by long periods of silence. Another example is the 33 responses of "electrocautery" to the Nellcor pulse oximeter alarm. This alarm is a constant, broadband sound that is similar to the "buzzing" of electrocautery. There were 327 relevant confusions that we believed could be attributed, at least in part, to sound confusion.

The second cause of mismatches was function confusion. This occurred when the subject attributed an alarm to another piece of equipment with a similar clinical function. Each alarm was classified as being in one or more of the following function categories: gas concentration, pressure, circuit disconnect, power loss, oxygenation, ventilation, circulation, and temperature. Table 3 displays our data grouped by function categories to highlight the areas of potential confusion. Examples are the confusions among the gas analyzers: the Miniox oxygen analyzer, the Ohmeda oxygen analyzer, the Datex airway gas monitor, and the SARA mass spectrometer. Another function confusion, which may be more difficult to appreciate, is the anesthetist's response of "airway pressure" to the Ohmeda Modulus I low-oxygen-supply pressure alarm; however, these are both pressure alarms. There were 202 relevant confusions that we believed could be attributed, at least in part, to function confusion.

In this retrospective analysis of relevant confusions, 36% were due to sound confusion, 15% to function confusion, 21% to both, and 28% to neither. Function confusions suggest that clinicians mentally group alarm sounds by monitor function. This may be advantageous in the clinical environment, because attention is directed to the appropriate system. It also reinforces the position that alarm sounds should be grouped by function (13). Our results indicate that the recognition rate for the alarm's function could be readily increased to 55% (the number of correct responses plus the number of relevant confusions due to function confusion) if alarms with similar functions had similar sounds.

Table 3. Clinicians' identification of alarm sounds, grouped by function categories. Correct responses are outlined on the *main diagonal*. Relevant confusions are in *bold type*. *Shading* indicates a functional similarity between the devices on the vertical and horizontal axes.

Our study has a number of potential design flaws. First, recorded alarms were used rather than the sounds from the actual machines. However, the investigators compared high-quality cassette recordings and digital recordings with the original sounds and believed that the digital system had superior playback sound quality. Even so, any sound recording and playback has the potential for distortion, and 13 of the subjects believed that the quality of the recordings interfered with their ability to recognize at least some of the alarms.

Second, the 19 alarms that we recorded would not all be present during a single operative case. Although all of the devices are used at our institution, there are variations in equipment among operating rooms. For example, we tested the alarms from two different oxygen analyzers, although only one model would be used in any single case. This artificially increased the number of possible alarms and may have interfered with the use of a situational factor in the recognition of alarms. Experienced clinicians anticipate foreseeable problems better than trainees do (14). Thus, a situational factor may be used by the experienced clinician in that he or she may expect particular alarms at certain phases during the course of an operation or may not consider alarms from equipment not currently in use. There may also be other factors, such as stage of the operation or patient illness, that cue the experienced clinician to particular monitors and alarms.

We conclude that current operating room alarms cannot be reliably recognized by sound characteristics alone. Some sounds are better recognized than others, and anesthetists mentally group alarm sounds by function.

Variation in Arterial to End-Tidal CO_2 Tension Differences During Anesthesia in the "Kidney Rest" Lateral Decubitus Position

Jean Louis Pansard, MD, Bernard Cholley, MD, Catherine Devilliers, PharmD,
François Clergue, MD, and Pierre Viars, MD

Département d'Anesthésie-Réanimation and Laboratoire des Urgences, Hôpital Pitié-Salpétrière, Paris, France

The course of arterial to end-tidal carbon dioxide tension difference [$P(a\text{-}ET)CO_2$] was evaluated during general anesthesia in 25 patients scheduled for renal surgery performed in the "kidney position." The difference between arterial PCO_2 ($PaCO_2$) corrected to body temperature, and end-tidal PCO_2 ($PETCO_2$) measured by mass spectrometry was assessed after induction of anesthesia, after placement in the lateral decubitus position with back arched over a kidney bridge ("kidney position"), and every 20 min until the patients were replaced in the supine position at the end of the surgical procedure. Heart rate, arterial blood pressure, and esophageal temperature were simultaneously recorded. After induction of anesthesia, when the patients were lying supine (T1), $P(a\text{-}ET)CO_2$ was 4.8 ± 3.9 mm Hg (mean ± SD). Placing the patients in the kidney position (T2) induced a significant increase in $P(a\text{-}ET)CO_2$ (to 7.9 ± 3.5 mm Hg; $P < 0.01$). These alterations occurred without any significant change in mean arterial blood pressure or heart rate. A progressive increase in mean $P(a\text{-}ET)CO_2$ occurred with maintenance of anesthesia; $P(a\text{-}ET)CO_2$ reached 8.8 ± 4.1 mm Hg ($P < 0.05$ vs T2) and 8.9 ± 4.4 mm Hg ($P < 0.05$ vs T2) at 65 and 85 min, respectively, after lateral decubitus positioning. Large variations between and within patients were observed. Although stable mean arterial pressure was maintained, these changes were associated with a significant decrease in body temperature. These results demonstrate that $P(a\text{-}ET)CO_2$ increases when patients are placed in the kidney position and may vary with the prolongation of anesthesia in this situation. Thus, $PETCO_2$ can be affected by position, and thus may not be constantly of value when estimating $PaCO_2$ during anesthesia.

(Anesth Analg 1992;75:506–10)

The monitoring of expired carbon dioxide concentration is becoming increasingly commonplace in the operating room. Intraoperative mishaps, such as inadvertent esophageal intubation, valve dysfunction, or disconnection from the ventilator, may be accurately detected with capnography (1–3). Moreover, measurement of end-tidal partial pressure of carbon dioxide ($PETCO_2$) has been recommended for the noninvasive estimation of $PaCO_2$ (4–6). Especially during anesthesia, $PETCO_2$ generally underestimates $PaCO_2$ (7,8), and the arterial to end-tidal difference $P(a\text{-}ET)CO_2$ varies between patients (8,9). The $P(a\text{-}ET)CO_2$ value depends on the alveolar dead space, which in turn is mainly influenced by the relative distribution of ventilation and perfusion (V/Q) within the lungs (10). Changes in these variables can induce variations in $P(a\text{-}ET)CO_2$. Patients scheduled for renal surgery via the lateral decubitus position are lying on their sides arched over a "kidney bridge," and the hips are somewhat flexed. We hypothesized that this kidney position could alter the $P(a\text{-}ET)CO_2$ value. Lateral decubitus positioning is known to impair ventilation/perfusion relationships in anesthetized patients (11,12). Further, the bridge may decrease venous return and increase the physiologic dead space (13). These alterations probably modify the $P(a\text{-}ET)CO_2$ difference, but this phenomenon has not been investigated.

Stability of arterial to end-tidal gradients within individual patients throughout a surgical procedure remains controversial. Some authors did not identify large modifications during maintenance of anesthesia (4,14), whereas others reported important variations within individual patients (15–17). These variations have been demonstrated in situations, such as cardiac and aortic surgery (15,16) or laparoscopy (17), where important disorders in hemodynamic status

or CO_2 production, respectively, occur. The course of P(a-ET)CO_2 during maintenance of anesthesia is not well characterized in patients who do not undergo such intraoperative hemodynamic alterations (13,14) but are subjected to potentially physiologically disruptive positions during surgery.

Therefore, the aims of this study were to determine the consequences of the kidney position on P(a-ET)CO_2 in patients scheduled for renal surgery and to monitor the evolution of this gradient during the surgical procedure in these patients.

Methods

Patients

Thirty-five patients (20 men, 15 women; mean age 58 ± 18 yr) were included in the study after approval by the ethical committee of the Pitié-Salpêtrière Hospital, and informed consent was obtained. All had preoperative vital capacity and forced expiratory volume in 1 s within the normal range. All were free of cardiac disease; six were smokers. They were scheduled for renal or upper ureteral surgery to be performed via the lateral decubitus position.

Measurements

Blood gas analysis was performed on samples drawn from an indwelling radial artery catheter inserted under local anesthesia before induction of general anesthesia. Syringes were rinsed with sodium heparin to prevent coagulation. Blood gases were analyzed at 37°C, but all values were corrected automatically for body temperature according to the following formula (18):

$$PaCO_2\ (\text{mm Hg}) = PaCO_2\ (37°\text{C}) \times 10^{0.019(t° - 37)},$$

where t° is patient temperature. The P(a-ET)CO_2 difference was calculated with the temperature-corrected $PaCO_2$ value.

Expired gas tension was measured with a mass spectrometer. Calibration with known gas mixture was carried out periodically according to manufacturer specifications. Samples were drawn from a manifold located at the proximal end of the tracheal tube. The mean $PETCO_2$ value was determined by averaging the values obtained during the 15 s immediately before the collection of arterial blood. The P(a-ET)CO_2 was calculated as the difference between arterial and expired CO_2 partial pressures obtained simultaneously.

Arterial pressure was continuously measured from the radial artery catheter. Heart rate was obtained from the electrocardiogram monitored with the V_5 derivation. Body temperature was assessed with a Hewlett-Packard esophageal thermistor probe.

Procedure

In all subjects, anesthesia was induced with fentanyl (2 μg/kg) and thiopental (5 mg/kg). Tracheal intubation was facilitated with vecuronium (0.1 mg/kg). Patients were mechanically ventilated at a respiratory rate of 14 breaths/min with a tidal volume of 8 mL/kg. After induction of anesthesia, to facilitate the surgical procedure, the patients were positioned on their side and arched over a "kidney bridge" break in the table, with their hips flexed 30° vertically. Anesthesia was maintained with 60% nitrous oxide in oxygen, isoflurane, and fentanyl. Anesthetic agents were administered as required to avoid variations in mean arterial pressure >10% of stabilized values recorded after induction of anesthesia.

Measurements, including $PaCO_2$, $PETCO_2$, mean arterial pressure, heart rate, and temperature, were first performed in the supine position 10 min after induction of anesthesia, when hemodynamic status was stabilized. The patients were placed in the kidney position, and a second set of measurements were performed 5 min later. The same variables were then recorded at approximately 20-min intervals throughout the duration of surgery. Isoflurane and nitrous oxide were stopped after wound closure. The patients were replaced in the supine position, and a final set of measurements was obtained 5 min later.

Statistical Analysis

Data were analyzed with a two-way analysis of variance for repeated measurements. When *P* values were <0.05, the Student-Newman-Keuls multiple-range test was used to assess differences within groups. All results are reported as mean ± SD.

Results

Results of mean $PaCO_2$, $PETCO_2$, P(a-ET)CO_2, heart rate, temperature, and mean arterial pressure measurements are presented in Table 1. The duration of surgery ranged from 70 to 160 min (mean, 102 ± 41 min). Thus, only five measurements were obtained after the same duration of anesthesia in all patients (T1–T5); T6 and T7 represent values obtained just before and after the subjects were again placed in the supine position, respectively. Mean P(a-ET)CO_2, observed after induction of anesthesia (T1), was 4.8 ± 3.9 mm Hg, but great variations between patients were observed, because the values ranged from −0.7 to 15 mm Hg. With lateral decubitus positioning (T2),

Table 1. Hemodynamic Variables in 35 Patients Undergoing Renal Surgery

Measurement	Paco$_2$ (mm Hg)	Petco$_2$ (mm Hg)	P(a-et)co$_2$ (mm Hg)	HR (beats/min)	MAP (mm Hg)	Temp (°C)
T1 (10 min after induction)	36.6 ± 5.6	31.4 ± 4.8	4.8 ± 3.9	69.7 ± 15	84.4 ± 18.9	36.3 ± 0.4
T2 (5 min after DLP)	35.5 ± 4.3	27.7 ± 4.1^{a}	7.9 ± 3.5	64.4 ± 11	83.2 ± 11.4	35.9 ± 0.5
T3 (25 min after DLP)	34.9 ± 4.8	26.9 ± 3.7^{a}	8.2 ± 4.3^{a}	62.5 ± 13	85.2 ± 9.8	35.5 ± 0.5^{a}
T4 (45 min after DLP)	34.6 ± 4.8	26.2 ± 3.7^{a}	8.5 ± 4.1^{a}	64.5 ± 13	86.6 ± 13.5	35.2 ± 0.5^{a}
T5 (65 min after DLP)	34.1 ± 5.1	25.4 ± 4.1^{a}	8.8 ± 4.1^{a,b}	61.9 ± 11	86.5 ± 12.1	34.9 ± 0.5^{a}
T6 (after skin closure)	34.1 ± 5.2	25.4 ± 3.7^{a}	8.9 ± 4.4^{a,b}	61.5 ± 11	88.1 ± 13.1	34.8 ± 0.6^{a}
T7 (5 min after supine replacement)	34.6 ± 6.3	27.8 ± 5.5^{a,c}	6.9 ± 5^{a,c}	70.2 ± 16^{c}	99.2 ± 17.1^{c}	34.6 ± 0.6^{a}

DLP, decubitus lateral positioning; HR, heart rate; MAP, mean arterial pressure; Paco$_2$, arterial partial pressure of carbon dioxide; Petco$_2$, end-tidal partial pressure of carbon dioxide; P(a-et)co$_2$, arterial to end-tidal difference in partial pressure of carbon dioxide; Temp, temperature.

Data are mean ± sd.

[a] $P < 0.01$ vs T1.

[b] $P < 0.05$ vs T2.

[c] $P < 0.05$ vs T6.

P(a-et)co$_2$ increased to 7.9 ± 3.5 mm Hg ($P < 0.01$). The Petco$_2$ significantly decreased (from 31.4 ± 4.8 to 27.7 ± 4.1 mm Hg; $P < 0.01$), whereas Paco$_2$ did not significantly change. Further variations in alveolar-arterial gradient were observed with the maintenance of anesthesia, because a significant increase in mean P(a-et)co$_2$ was observed at T5 and T6 compared with T2 values (8.8 ± 4.1 and 8.9 ± 4.4 mm Hg, respectively; $P < 0.05$). Although the mean change in P(a-et)co$_2$ value was trivial but significant, large variations were observed between patients. The mean difference between gradient value at T6 and T2 was 1.18 ± 2.2 mm Hg (mean ± sd), and values ranged from −1.3 to 8.2 mm Hg. Furthermore great variations existed within patients. To illustrate this phenomenon, the difference between the greatest and the lowest gradient obtained between T2 and T6 was calculated patient by patient (Δgradient). The Δgradient ranged from 2.1 to 10.8 mm Hg (5.35 ± 2.65 mm Hg [mean ± sd]). When the patients were placed again in the supine position (T7), P(a-et)co$_2$ decreased (from 8.9 ± 4.4 to 6.9 ± 5.0 mm Hg; $P < 0.05$), whereas mean arterial pressure increased significantly (from 88.1 ± 13.1 to 99.2 ± 17.7 mm Hg; $P < 0.01$). Except for this last value, mean arterial pressure and heart rate remained constant throughout the study, but esophageal temperature dramatically decreased from 36.3 ± 0.4°C to 34.6 ± 0.6°C ($P < 0.001$).

Discussion

This study demonstrates that in anesthetized patients, the kidney position induces an increase in P(a-et)co$_2$. Further in this situation, the gradient may vary with prolongation of anesthesia despite the hemodynamic status remaining stable.

Several studies have been performed to evaluate the difference between arterial and end-tidal CO$_2$ measurements in adults or children under general anesthesia (4,8,14–17); values between 3 and 5.2 mm Hg have been reported. This variable was generally obtained with the patients lying supine. The mean P(a-et)co$_2$ of 4.8 mm Hg obtained after induction of anesthesia in this study compares reasonably well with the measurements of others. Consequences of other positions on P(a-et)co$_2$ have not been precisely evaluated. The enlargement in P(a-et)co$_2$ observed after positioning could be related to the alterations in ventilation/perfusion relationship that are known to occur in the lateral decubitus position. The anesthetized patient in the lateral decubitus position, with or without paralysis, has a nondependent lung that is well ventilated but poorly perfused, whereas the dependent lung is well perfused but poorly ventilated (11,19). This results in an increased degree of mismatching of ventilation and perfusion. As a result, the dead space increases, leading to an enlarged P(a-et)co$_2$. Lateral decubitus positioning has been shown to produce an increase in physiologic dead space between 0% and 13% (20–22); however, the kidney position used for renal surgery probably induced more extensive respiratory disturbances than the standard lateral decubitus position. Indeed, the patients were lying on their side but arched over a "bridge," with flexed hips. Thus, possible hemodynamic alterations could also be involved in the gradient variations observed with positioning. Mean arterial pressure was stabilized close to the supine values before the P(a-et)co$_2$ was measured. Right filling pressure or cardiac output, or both, which were not monitored, could have decreased. Because changes in either of these two variables can induce alterations in alveolar dead space (23,24), P(a-et)co$_2$ therefore could have been enlarged. Also, the bridge break in the table may result in compression of the base of the dependent lung and produce additional impairment in ventilation/perfusion relationships. Because of ethical considerations, cardiac output and filling pressures were not invasively monitored in this study. Thus, we were unable to determine whether hemodynamic alterations or changes in distribution of ventilation, or both, were responsible for gradient alterations.

Continued changes in P(a-ET)CO_2 were observed with prolongation of anesthesia. After the patients were positioned, the gradient progressively increased and became significantly greater 60 min later. Controversy persists with regard to stability of P(a-ET)CO_2 during anesthesia. Whitesell et al. (4) found that P(a-ET)CO_2 remained relatively constant with maintenance of anesthesia and could be applied as a correction to subsequent peak expired values to predict arterial CO_2. However, the delay between initial and subsequent measurements was not mentioned in their study and could have been insufficient to discover gradient variations. In contrast, Raemer et al. (15) observed important gradient variability between and within 15 patients during aortic or cardiac surgery. They could not identify which variable among arterial pressure, temperature, anesthesia duration, or minute ventilation was responsible for these variations. In our study, P(a-ET)CO_2 increased significantly during anesthesia. Although the mean increase was clinically trivial but statistically significant, there were some large variations in P(a-ET)CO_2 observed between and within patients. Many factors could be involved in this phenomenon. Despite arterial blood pressure stability, hemodynamic alterations probably occurred, because all patients presented some degree of hemorrhage during the time-course of the surgical procedure. Blood losses were compensated by plasma volume expansion or transfusion when necessary. Changes in cardiac output or filling pressures clearly could have occurred, resulting in modified alveolar dead space. This factor could contribute to both a progressive increase and to variations in P(a-ET)CO_2 within patients.

The progressive hypothermia observed in this study could have influenced P(a-ET)CO_2 values. Because gas solubility, pH, and pK of carbonic acid all change with temperature, there is a substantial physiologic decrease in PaCO_2 with hypothermia for a given CO_2 content of blood (25,26). To limit the influence of this variable on P(a-ET)CO_2 determination, arterial PaCO_2 values were measured at 37°C but corrected to patient temperatures before gradient calculation, because the use of the noncorrected PaCO_2 for P(a-ET)CO_2 calculation would have artificially increased the gradient value.

The alterations in P(a-ET)CO_2 could also be related to an impairment in gas exchange occurring with prolongation of anesthesia (27). Gunnarsson et al. (28) observed that patients under enflurane/nitrous oxide anesthesia exhibited significant increases in shunt and large increases in atelectasis between 30 and 90 min after induction of anesthesia. The influence of shunt on P(a-ET)CO_2 is probably trivial (29,30), but such alterations could influence the variations observed in this study.

The final set of measurements in our study was obtained when the patients were placed again in the supine position. Isoflurane was interrupted at this moment in all patients, which explains the increased arterial blood pressure, probably associated with increased cardiac output. These two phenomena, by reducing physiologic dead space (13,23), probably contributed to the decrease in P(a-ET)CO_2 observed at this time.

In conclusion, this study demonstrates that P(a-ET)CO_2 increases when patients are placed in the kidney position necessary for renal surgery. This phenomenon illustrates the respiratory and circulatory alterations likely to occur as a result of this position. Further, in this situation, the arterial to end-tidal CO_2 gradient may vary with prolongation of anesthesia. We do not believe it is valid to assume that a constant arterial to end-tidal CO_2 gradient exists when estimating PaCO_2 from PETCO_2 when the patient is in the lateral decubitus kidney position.

Effect of Electroconvulsive Therapy on the Electrocardiogram and Echocardiogram

Anthony G. Messina, MD, Mary Paranicas, BA, Barri Katz, MD, John Markowitz, MD, Fun-Sun Yao, MD, and Richard B. Devereux, MD

Departments of Anesthesiology, Psychiatry, and Medicine, The New York Hospital-Cornell University Medical College, and Department of Anesthesiology, Lenox Hill Hospital, New York, New York

Although electrocardiographic (ECG) ST segment depression is commonly induced by electroconvulsive therapy (ECT) for depression, it is unknown whether this reflects segmental myocardial ischemia, as is true under most circumstances, or a direct effect of central nervous system stimulation on cardiac repolarization in the absence of ischemic left ventricular regional wall motion abnormalities. We evaluated the association between ECG changes and left ventricular regional wall motion abnormalities detected by the echocardiograms performed before and after ECT in 11 patients. Immediately after ECT, three patients' ECGs revealed 1-mm downsloping or horizontal ST segment depression, one had a nonspecific ECG change (peaked T waves), and the ECG remained normal in seven. All patients had normal baseline echocardiograms. After ECT, at a time when the product of arterial blood pressure and heart rate was 100% above baseline values, five patients developed new left ventricular regional wall motion abnormalities that were confined to hypokinesia; no patient developed myocardial infarction or angina after ECT. Three patients with regional wall motion abnormalities developed ECG ST segment depression after ECT (sensitivity 60%), one had a nonspecific ECG change (peaked T waves), and the ECG of one patient remained normal. In conclusion, ECT may induce ECG changes with simultaneous regional wall motion abnormalities at a time when arterial blood pressure and heart rate are markedly elevated, findings that are highly suggestive of "demand" myocardial ischemia. In this small series, ECG or echocardiographic abnormalities did not predict clinical cardiac morbidity.

(Anesth Analg 1992;75:511–4)

Electroconvulsive therapy (ECT) has been advocated as the antidepressant therapy of choice in cardiac patients because of the cardiotoxic effects of psychotropic drugs (1); however, electrocardiographic (ECG) changes have been reported with ECT (2). Whether ECG changes observed with ECT or various neurologic diseases represent myocardial ischemia remains controversial, as do the mechanisms responsible for these changes (1,3,4). We used transthoracic echocardiograms immediately before and after initial ECT treatment with simultaneous ECG recording to determine whether ECG changes observed during ECT were accompanied by left ventricular regional wall motion abnormalities suggestive of segmental myocardial ischemia.

Methods

Twenty patients with mood disorders undergoing ECT were studied after giving informed written consent under a protocol approved by the Committee on Human Rights in Research of Cornell University Medical College. Pre-ECT or post-ECT (or both) echocardiograms in 9 patients were of insufficient quality to permit complete analysis, leaving 11 patients with complete studies. The patients (seven women, four men) ranged in age from 33 to 79 yr, with a mean of 54 yr. Five patients were receiving combinations of diuretics, angiotensin-converting enzyme inhibitors, and β-adrenoceptor or calcium-channel blocking drugs. Two patients had a history of myocardial infarction that clinically had been small in size. Eight of the 11 patients had at least one risk factor for atherosclerosis: hyperlipidema, hypertension, cigarette smoking, male gender, or diabetes mellitus. Eight patients had a family history of cardiac disease, five had at least one abnormality on their pre-ECT electrocardiogram (nonspecific repolariza-

Nonspecific ECG change (n = 1)		1	1	1
Normal ECG response (n = 7)	6	1	5	5

ECG, electrocardiographic; ECHO, echocardiographic; ECT, electroconvulsive therapy; Pts, patients; RWMA, regional wall motion abnormalities.

tion abnormalities, n = 4; left ventricular hypertrophy, n = 1; or old myocardial infarction, n = 2).

Anesthesia administered consisted of intravenous thiopental (125–175 mg) and succinycholine (50–80 mg) and inhalation of 100% oxygen by a face mask. One patient received atracurium (25 mg IV) instead of succinycholine because of a history of poliomyelitis. Manual arterial blood pressure, lead II of the ECG, pulse oximetry, and echocardiographic monitors were used. Before anesthetic drugs were administered, baseline recordings of arterial blood pressure, heart rate, and lead II of the ECG were made. In addition, oxygen saturation (measured by pulse oximeter) and transthoracic two-dimensional long- and short-axis views of the left ventricle were recorded with an Acuson 128 echocardiograph. Bilateral ECT was delivered with use of standard placements and a MECTA SR device (5).

Beginning immediately after the induced seizure had ended, arterial pressure, heart rate, ECG waveform, and oxygen saturation were repeatedly measured at 1-min intervals and echocardiographic imaging every 2 min until all variables returned to baseline. Echocardiograms were interpreted in a blinded fashion and in random order by two experienced investigators unaware of the hemodynamic measurements and the course of the ECT treatment. The left ventricle was divided into 14 segments, and wall motion was graded as normal, hypokinetic, akinetic, or dyskinetic (6).

The association between regional wall motion abnormalities and ECG changes induced by ECT was tested by the χ^2 statistic with Yates' continuity correction, as were the associations between conventional cardiac risk factors and induced ECG and echocardiographic changes. Echocardiographic segmental regional wall motion abnormalities induced by ECT were used as the reference standard to calculate the sensitivity and positive predictive value of ECG changes by standard statistical definitions (7).

Results

In our 11 patients, 143 of 154 (93%) possible left ventricular (LV) wall regions were examined. Before ECT, all myocardial segments were normal. Immediately after ECT, five patients (45%) had hypokinesis of one or more contiguous myocardial segments involving the LV apex in three, the inferolateral wall in one, and the anteroseptal LV wall in one.

Immediately after ECT, diastolic and systolic arterial blood pressure and heart rate increased from baseline values in all 11 patients (from 129/82 ± 22/8 to 175/97 ± 20/11 mm Hg [mean ± SD], $P < 0.0001$ (systolic blood pressure)/0.0018 (diastolic pressure), and from 81 ± 7 to 127 ± 21 beats/min, $P < 0.0001$, respectively). Arterial pressure and heart rate had risen from baseline values of 132/79 ± 17/2 to 184/98 ± 15 mm Hg, $P < 0.001/0.041$, and 81 ± 8 to 118 ± 14 beats/min, $P < 0.018$, respectively, in the five patients who developed new segmental LV hypokinesia. Parallel changes in arterial blood pressure and heart rate from baseline to 2 min after ECT in the six patients who did not develop new regional wall motion abnormalities were from 127/84 ± 26/10 to 168/96 ± 21/7 mm Hg, $P < 0.002/0.028$, and from 80 ± 8 to 133 ± 25 beats/min, $P < 0.003$. All induced regional wall motion abnormalities occurred simultaneously, with substantial increases in heart rate and blood pressure. Oxygen saturation was maintained in the normal range (98%–99%).

Of the five patients in whom function of one or more initially normal LV segments deteriorated by one grade to hypokinesis, three developed new ECG changes suggestive of ischemia, with ≥1-mm horizontal or downsloping ST depression. In another of these five patients, the ECG revealed nonspecific repolarization abnormalities (peaked T wave). In seven patients, the ECG remained normal. All induced regional wall motion abnormalities and ECG changes occurred in the first 2–4 min after ECT, whereas arterial pressure and heart rate were near maximal values. The double product of heart rate and systolic pressure had increased by 103% over baseline at the time of these abnormalities. As Table 1 reveals, LV regional wall motion abnormalities were detected by echocardiography in all four patients in whom ECG abnormalities were induced by ECT but in only one of seven patients whose lead II recording remained normal ($\chi^2 = 4.88$, $P < 0.05$). Prevalence of conventional coronary risk factors and family history of heart disease was similar in patients with and without inducible ECG change or regional wall motion abnormality (χ^2 statistics = 0.003–0.88, all $P > 0.25$).

All ECGs and echocardiograms returned to baseline by the end of the study. No patient had a myocardial infarction. All patients' mood disorders improved with ECT.

Discussion

In the present study, we document the simultaneous induction of LV regional wall motion abnormalities and ECG changes during ECT. Regional wall motional abnormalities observed in our patients were limited to hypokinesia, with no akinesia or dyskinesia. Global LV hypokinesia may reflect altered loading conditions, and regional myocardial hypokinesia may be due to major ECG conduction defects rather than myocardial ischemia (8,9). The LV wall motion abnormalities induced by ECT in our patients were regional rather than global, occurred in regions corresponding to coronary artery distributions, and were not accompanied by major ECG conduction defects. There was a moderate and statistically significant concordance between ECG and echocardiographic changes during ECT in this patient population (Table 1). These characteristics of the induced wall motion abnormalities make it highly likely that they reflected segmental myocardial ischemia provoked by ECT.

Treadmill exercise testing is the test most commonly used to diagnose coronary artery disease (10). The stress of ECT on the heart, with marked increases in blood pressure and heart rate, has certain similarities to those imposed by treadmill exercise testing: both procedures may produce ST-T wave abnormalities and, as demonstrated in this study for ECT, regional wall motion abnormalities. However, treadmill testing uses aerobic exercise, whereas ECT induces central nervous system-mediated adrenergic hyperactivity and increased catecholamine release, as has been documented from our center in similar patients undergoing ECT by the same protocol (11). Testing by means of exercise and other stressors has shown that regional wall motion abnormalities are rare in truly normal individuals but are more common with early cardiomyopathy or angina with normal large coronary arteries ("syndrome x"). Overall, the positive predictive value of regional wall motion abnormalities seen at rest or developing during exercise echocardiography for detecting coronary artery disease on angiography is 80%–95% (10,12). Mild apical hypokinesia at peak exercise may be seen in patients with LV enlargement caused by severe valvular regurgitation, which was not present in any of our patients. Therefore, the occurrence in three of our patients who underwent ECT of both ST depression and regional wall motion abnormalities is highly suggestive of myocardial ischemia.

A limitation of our study was the difficulty in obtaining high-quality two-dimensional echocardiograms before and immediately after the acute stress of ECT. In contrast to the at least 80% success rate in obtaining fully adequate two-dimensional echocardiograms in middle-aged to elderly patients (13), the technical restrictions imposed by fasciculations due to succinylcholine and the rapidly changing study conditions after ECT reduced to 55% our yield of adequate studies. The excluded patients were similar in age, gender, risk factors, and incidence of ECG abnormalities to the patients with adequate echocardiograms. In addition, the sensitivity of our study may have been limited because only lead II of the ECG was used. One patient in the present study had peaked T waves after ECT treatment, with simultaneous onset of hypokinesis in the apical septal portion of the left ventricle, suggesting that this ECG change may have reflected myocardial ischemia.

In conclusion, our results document that ECG ST segment depression or other repolarization abnormalities provoked by the stress of ECT are associated with LV regional wall motion abnormalities. These appear to reflect "demand" myocardial ischemia, because they occur with marked blood pressure and heart rate increases at a time of documented intense adrenergic nervous system activation. Larger studies are needed to determine whether LV regional wall motion abnormalities provoked by ECT predict clinically significant complications of the procedure, and if so, to assess whether they can be prevented by medications such as short-acting β-blockers without exacerbating the underlying depression for which ECT is used.

The authors thank Drs. John Savarese and Stephen Thomas for reviewing the manuscript.

---

A bilateral cemented arthroplasty (BCA) in anesthetized mongrel dogs creates pulmonary fat and marrow embolism. A transient increase in plasma concentration of 6-keto prostaglandin $F_{1\alpha}$ and thromboxane B_2 has been associated with hemodynamic instability after BCA. We tested whether intravenous ibuprofen (20 mg/kg) could inhibit prostaglandin production, pulmonary hypertension, and decreased arterial blood pressure in this model. We found a decrease in cardiac output from 3.0 ± 0.5 to 2.2 ± 1.3 L/min (mean ± 1 SD) after BCA with a flow probe placed at thoracotomy around the ascending thoracic aorta. Systemic arterial blood pressure decreased from 140 ± 11 to 100 ± 15 mm Hg ($P < 0.0001$), and pulmonary artery pressure increased from 17.7 ± 3.3 to 37.1 ± 9.4 mm Hg ($P < 0.0001$). Similar hemodynamic changes were noted in 12 dogs without thoracotomy. Pretreatment with ibuprofen did not significantly attenuate the acute hemodynamic changes despite inhibiting prostaglandin generation. We conclude that decreased arterial blood pressure after BCA is associated with a decrease in cardiac output and that inhibition of prostaglandin production with ibuprofen does not prevent either pulmonary hypertension or systemic hypotension.

(Anesth Analg 1992;75:515–22)

Acute cardiopulmonary instability during cemented arthroplasty occurs at the time of cement and prosthesis insertion (1–3). Hemodynamic and gas-exchange abnormalities have been studied in patients (1–5) and in anesthetized animals (6) and are characterized by elevated pulmonary artery pressure (PAP) (6), reduced arterial blood pressure (BP) (1), and decreased systemic arterial oxygen tension (Pa_{O_2}) (3). Although hypotension is often transient, the cause of acute hemodynamic changes during cemented arthroplasty is important, because sudden cardiac arrest (5) and intraoperative deaths (7) have been reported. Intraoperative monitoring of patients during cemented arthroplasty with precordial Doppler (8) and transesophageal echocardiography (9) has detected pulmonary embolization of marrow contents.

Arachidonic acid metabolites are known to alter the vasoactive properties of both the pulmonary (10) and systemic (11) circulation. Infusion of fat and marrow emboli from donor animals causes an increased concentration of arachidonic acid metabolites detected in pulmonary lymph and blood (12,13). A simulated cemented arthroplasty procedure in anesthetized mongrel dogs has demonstrated an acute, transient increase in plasma thromboxane B_2 and 6-keto prostaglandin $F_{1\alpha}$ ($PGF_{1\alpha}$) accompanying fat embolism in vivo (14). Whether this prostanoid response to fat emboli contributes to hypertension by prostacyclin-induced vasodilation or to pulmonary hypertension by thromboxane A_2-induced vasoconstriction has not been studied. Patients having cemented arthroplasty procedures are often pretreated with ibuprofen, a nonsteroidal antiinflammatory drug that inhibits prostaglandin generation. This study evaluates whether ibuprofen could reduce pulmonary hypertension or systemic hypotension after cemented arthroplasty and reports acute changes in cardiac output associated with the decreased BP, pulmonary hypertension, and prostaglandin release in this model.

Methods

This study was approved by the local animal care committee, and all dogs were treated in accordance

with the regulations of the Canadian Council on Animal Care. Twenty-one mongrel dogs weighing 28.5 ± 5.4 kg were anesthetized with intravenous pentobarbitone (30 mg/kg), followed by a continuous infusion ($0.5\ mg \cdot kg^{-1} \cdot h^{-1}$) of pentobarbitone, as required to maintain anesthesia and a stable hemodynamic state. The trachea was intubated in each animal. The lungs were mechanically ventilated with a nonrebreathing circuit using room air. Ventilation was adjusted before surgery to keep arterial blood Pco_2 at 35–40 mm Hg. Animals were paralyzed with pancuronium bromide (0.2 mg/kg), and lactated Ringer's solution was infused intravenously at a rate of $10\ mL \cdot kg^{-1} \cdot h^{-1}$ to maintain intravascular volume during the procedure.

Surgical exposure of both distal femoral condyles preceded physiologic measurements. In the control group of animals, prereaming measurements were made; then both femoral condyles were drilled and reamed retrogradely to a depth of 10 cm with successively larger reamers until a size 9 reamer was readily inserted. After reaming, all physiologic measurements were repeated (postreaming values). After the postreaming measurements were made, a bilateral cemented arthroplasty (BCA) was performed by injecting low-viscosity bone cement, mixed according to standard directions, into both intramedullary canals under manual pressure. Solid contoured metal prostheses were then hammered simultaneously into both intramedullary cavities to simulate prosthesis insertion. All measurements were repeated at predetermined intervals after BCA, as specified in the protocol.

Dogs were divided into two groups: the control group (*n* = 12) and the ibuprofen-pretreated group (*n* = 9). In both groups, the surgical technique and physiologic and pathological measurements used were standardized and are described later. The plasma assays and quantitative morphometric measurements were reported without previous knowledge of animal pretreatment.

In the control group (*n* = 12), a BCA procedure was performed without any prior drug administration. Control animals were treated with an infusion of saline solution (200 mL) over 20 min before BCA. In 6 of the 12 control animals, a thoracotomy was performed to place an ultrasonic flow probe around the ascending intrathoracic aorta. The flow probe measured pulsatile cardiac output. The other six animals in the control group had a BCA performed with an intact chest wall and intermittent measurement of cardiac output using the thermodilution technique.

The ibuprofen group (*n* = 9) received ibuprofen (20 mg/kg) diluted in 200 mL of saline solution administered intravenously before BCA. In three of the nine ibuprofen-pretreated animals, a thoracotomy was performed before BCA to place the ultrasonic flow probe around the ascending thoracic aorta to measure cardiac output. The animals with a thoracotomy were given ibuprofen after a set of predrug measurements and before reaming of the intramedullary canals. After the infusion of ibuprofen, a preream arterial blood sample was obtained to measure plasma thromboxane B_2 (TxB_2) and 6-keto $PGF_{1\alpha}$ concentrations. The intramedullary canals were then drilled and reamed, postreaming blood samples were taken, and a BCA was performed as described. The other six animals in the ibuprofen group were studied with an intact chest wall, and the ibuprofen was administered intravenously before baseline measurement to simulate preoperative ibuprofen therapy.

In all animals, the postreaming data serve as a baseline for comparison with subsequent measurements, because these measurements are taken after the blood loss of reaming and close in time to cement and prosthesis insertion, as previously described (6,14).

In all dogs, a 7F triple-lumen balloon-tipped pulmonary artery catheter was inserted into the left femoral vein and positioned in the pulmonary artery to measure PAP and right atrial pressure (RAP). The left carotid artery was cannulated with a pressure-tipped arterial catheter (Millar Instruments, Inc., Houston, Tex.), which was advanced into the ascending thoracic aorta to measure systemic arterial BP. All pressures were continuously recorded on a Gould ES 1000 recorder and are reported at 1, 5, and 15 min after BCA.

A left fifth interspace thoracotomy was performed in nine dogs: six control dogs and three dogs pretreated with ibuprofen. After incising the pericardium, a 7F catheter was sutured directly into the left atrium to monitor left atrial pressure (LAP) continuously. A T_{201} ultrasonic blood flowmeter (Transonic Systems, Inc., Ithaca, N.Y.) was placed around the ascending thoracic aorta to continuously measure pulsatile cardiac output (aortic flow).

In dogs without a thoracotomy (six control and six pretreated with ibuprofen), a Cordis 7F pigtail catheter was inserted through the carotid artery into the left atrium via the left ventricle. This catheter was used to measure LAP directly. Cardiac output was measured using thermodilution technique in triplicate at each measurement period. The mean of three determinations was used as representative of cardiac output at each measurement time. Because the thermodilution technique is most accurate if a stable hemodynamic state exists, we did not measure cardiac output at the 1-min time period in dogs without a thoracotomy.

We sampled arterial blood from the descending thoracic aorta for measurement of the plasma concentration of arachidonic acid metabolites, 6-keto $PGF_{1\alpha}$ and TxB_2. Blood samples were taken for plasma assays at the following time intervals: before reaming, immediately after reaming, 1, 5, and 15 min after BCA.

Each blood sample (9 mL) was collected in a plastic syringe containing 1 mL of an indomethacin/anticoagulant (ethylenediaminetetraacetate [EDTA]) solution. This solution was prepared by diluting (1:20) the stock indomethacin (0.04 M indomethacin in ethanol) in an EDTA anticoagulant. The anticoagulant was prepared by dissolving 2 g of disodium EDTA and 0.8 g of sodium chloride in 100 mL of water. The pH was adjusted to 7.4 by adding sodium hydroxide. Indomethacin was added to inhibit any further production of arachidonic acid metabolites in vitro after sampling. Each blood sample was then mixed and immediately transferred to a plastic centrifuge tube, centrifuged, and the plasma collected. The plasma was then transferred to polypropylene tubes and frozen immediately at −20°C for storage.

The plasma concentrations of the stable metabolite of thromboxane A_2, TxB_2, and 6-keto $PGF_{1\alpha}$, the stable metabolite of prostacyclin, were determined by radioimmunoassay. The radioimmunoassay kits used labeled I^{125} tracers from Dupont Canada. All plasma samples and standards were analyzed in duplicate. Samples were measured, and standard curves were constructed. The gamma counter was LKB model 1277 (Wallac Oy, Turku, Finland). The intra- and interassay coefficients of variation were, respectively, 7.6% and 6.1% for TxB_2 measurements and 4.0% and 9.4% for 6-keto $PGF_{1\alpha}$. Results from duplicate samples showed good reproducibility (<10% variation). The lowest level of detection with these methods was 0.005 ng/mL for TxB_2 and 0.01 ng/mL for 6-keto $PGF_{1\alpha}$.

After completing each study, the 12 anesthetized dogs without a thoracotomy (6 control and 6 ibuprofen pretreated) were killed by injecting pentobarbital (200 mg) and KCl through the left atrial cannula. A postmortem thoracotomy was performed and the pulmonary vessels ligated. The lungs were removed en bloc and fixed in inflation with 10% buffered formalin at a pressure of 25 cm of fixative. After fixation for 72 h, the lungs were sectioned in the midsagittal plane, and three stratified random blocks of known size were taken from the midsagittal slice of each lung. These samples were postfixed in Fleming's solution for 72 h, washed in running water for 24 h, processed for histologic examination in the usual manner, and cut at 5-μm thickness.

The sections were then evaluated with a TV-based image analysis system (BQ Meg IV, R and M Biometrics, Nashville, Tenn.). This system has a Leitz Dialux 22 microscope attached to a Sony CCD video camera connected to an IBM AT compatible microcomputer. For each animal, 12 stratified random fields (each 1 mm^2) from the six lung samples were examined for a total area of 72 mm^2 per animal. The measurements were made at a final optical magnification of 245×. The gray scale image was converted to a binary (black-and-white) image by manual selection of the threshold value that best delineated the emboli from background. The area and diameter of each embolus was calculated. The ratio of area occupied by fat emboli to total area of lung examined is equivalent to the volume proportion of lung tissue occupied by fat (Delesse's principle). The number of fat emboli and volume proportion of lung tissue occupied by fat after BCA in each group could then be compared.

Data are reported as mean values ± 1 SD. Data were analyzed with the SAS (Statistical Analysis Software) statistical software package. We used the SAS general linear model repeated measures analysis of variance procedure to analyze data from sequential measurements. When a significant F ratio was present ($P < 0.05$), multiple comparisons within groups between baseline (postream) and other measurements were made using unadjusted pairwise comparisons, as printed out by LSMEANS comparison procedure, with adjustment made on the probability of rejection with Bonferroni's correction (15). If there was significant group and time interaction, multiple comparisons with baseline values within groups were determined with Dunnett's test.

Results

There was no significant difference in the mean weight of dogs included in the control (27.8 ± 5.5 kg) and the ibuprofen-pretreated (26.4 ± 5.9 kg) groups. No difference was found between the baseline hemodynamic measurements of control and ibuprofen-treated dogs.

Control Group: Hemodynamic and Gas-Exchange Data

In the control group with a thoracotomy ($n = 6$), a significant decrease in mean BP was noted from 140 ± 11 mm Hg before BCA to a minimal value of 100 ± 15 mm Hg within 1 min of BCA. The aortic flow decreased in every control dog studied. In the control group, the aortic flow decreased ($P < 0.0002$) from a mean value of 3.0 ± 0.5 L/min after reaming to 2.2 ± 1.3 L/min within 2 min of BCA, returning to 2.7 ± 1.4 L/min by 5 min after BCA. This decrease in flow occurred simultaneously with an increase in PAP. Mean PAP increased significantly ($P < 0.0001$) from 17.7 ± 3.3 to 37.1 ± 9.4 mm Hg within 1 min of BCA

Table 1. Hemodynamic Data (mean ± SD) Before and After Bilateral Cemented Arthroplasty in 12 Dogs With Intact Chest Walls

	Preream	Postream	1–3 min after BCA	5 min after BCA
BP (mm Hg)

Ibuprofen	105.9 ± 3.6	107.9 ± 2.1	99.7 ± 6.8[a]	97.2 ± 3.6[a,b]

BCA, bilateral cemented arthroplasty; BP, arterial blood pressure; Control, control group (*n* = 6); Ibuprofen, ibuprofen (20 mg/kg)-pretreated group (*n* = 6); PAP, pulmonary artery pressure; RAP, right atrial pressure; LAP, left atrial pressure; Q, thermodilution cardiac output; Pa_{O_2}, arterial P_{O_2}.

[a] Significant difference from baseline (postream) values.

[b] Significant difference between groups at this measurement time.

and remained elevated at 28.0 ± 4.3 mm Hg at the 5-min measurement. Mean PAP remained elevated ($P < 0.0001$) throughout the 15-min study (26.7 ± 2.9 mm Hg). No changes in RAP or LAP were noted during the 15-min study period in this group.

In the six control dogs without a thoracotomy, the BP decreased significantly from a postream value of 148 ± 5 mm Hg to a minimal value of 120 ± 19 mm Hg approximately 1 min after BCA (Table 1). The BP returned to baseline levels within 5 min of BCA. The PAP increased ($P < 0.005$) after BCA, and no change in RAP or LAP was noted. Cardiac output was measured at the 5-min measurement period and was not significantly different from baseline value at this time, whereas PAP remained elevated above baseline value. The Pa_{O_2} decreased from baseline to both the 1- and 5-min measurements. No differences between pre- and postreaming (baseline) measurements were noted.

Ibuprofen Group: Hemodynamic and Gas-Exchange Data

No difference was noted in baseline measurements between the ibuprofen-pretreated dogs with a thoracotomy ($n = 3$) and the control group. Mean BP decreased from 168, 135, and 152 mm Hg before BCA to 138, 112, and 126 mm Hg, respectively, within 1 min of BCA in the three ibuprofen dogs. No change in LAP or RAP was found. The PAP increased within 1 min of BCA from 17.7, 11.3, and 16.0 mm Hg to 35.7, 36.3, and 27.3 mm Hg, respectively. Aortic flow decreased from 2.2, 2.9, and 3.2 L/min to 1.6, 2.3, and 2.8 L/min, respectively, after BCA. Cardiac output and BP returned to baseline levels within 5 min despite a persistent increase in PAP.

In ibuprofen-pretreated animals with an intact chest wall, no difference between the prereaming and postreaming measurements was noted (Table 1). The BP decreased from 145 ± 14 to 131 ± 17 mm Hg within 3 min of BCA, returning to baseline value by the 5-min measurement. The PAP increased from 14.2 ± 3.6 to 32.3 ± 6.9 mm Hg within 1 min of BCA. No change in RAP or LAP was noted. The cardiac output measured by thermal dilution technique at the 5-min measurement was not significantly different from the baseline value. No difference between groups was noted in the change of BP, PAP, or cardiac output from baseline. The Pa_{O_2} at the 1- and 5-min measurements was significantly different from the baseline value. The 1-min Pa_{O_2} was not significantly less than that noted in the control group at the same period; however, the 5-min Pa_{O_2} (97.2 ± 3.6 mm Hg) was significantly higher than that noted in control animals (87.6 ± 5.9 mm Hg).

Prostaglandin Assays

In the control group of animals that had a thoracotomy ($n = 6$), the plasma 6-keto $PGF_{1\alpha}$ concentra-

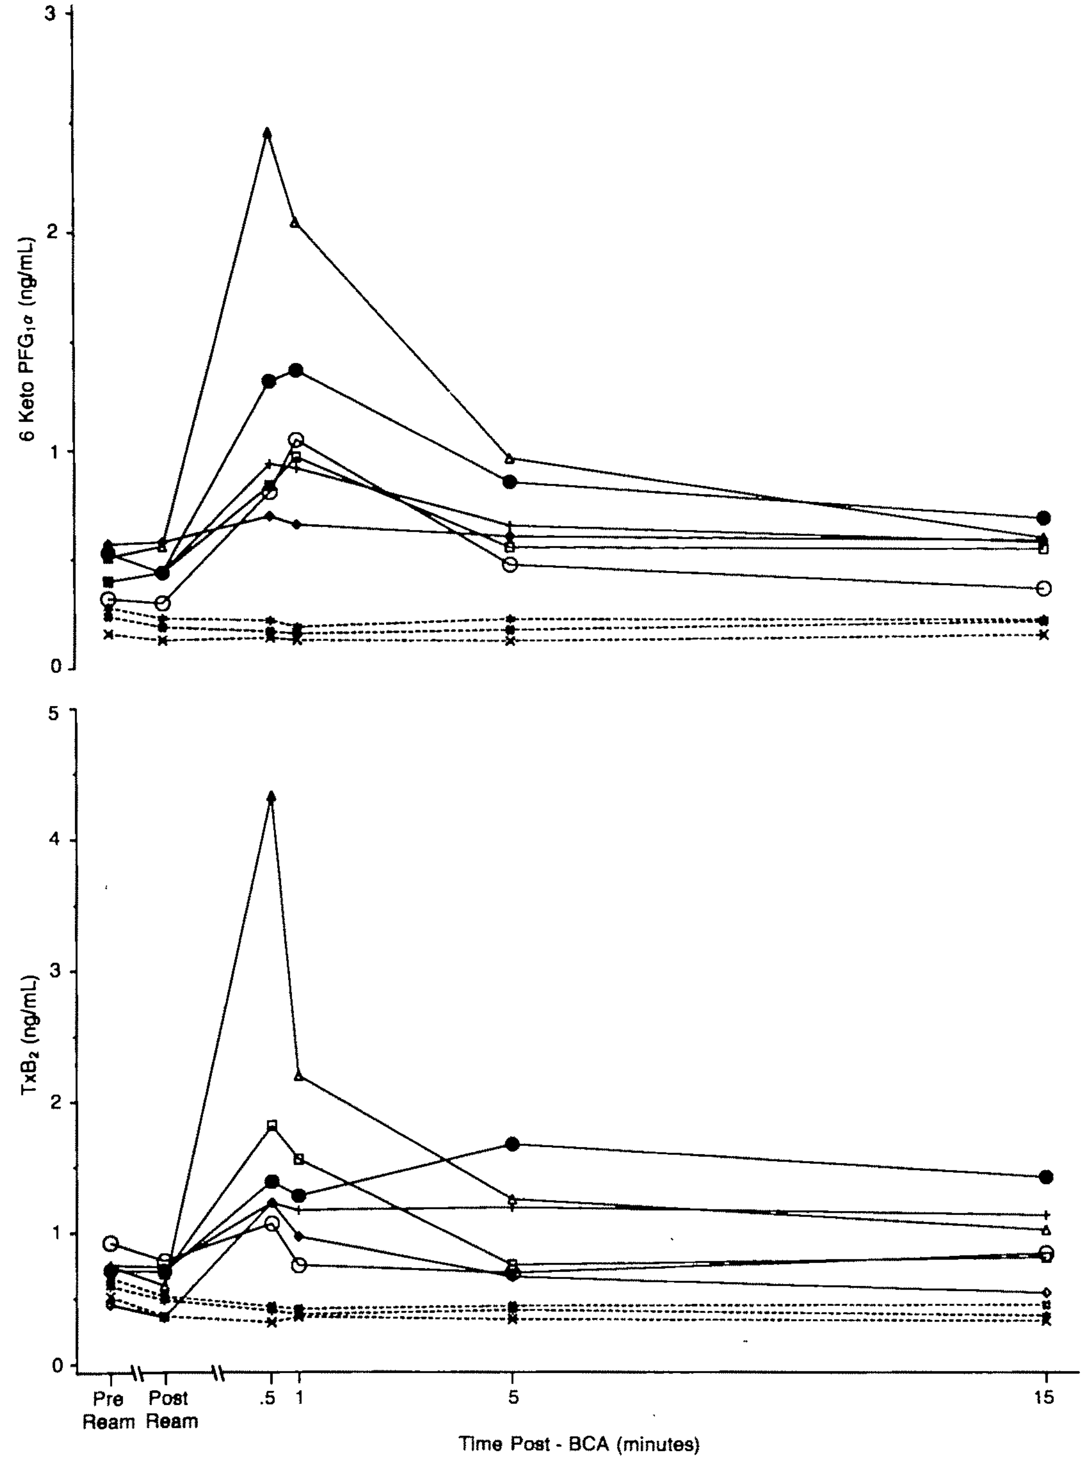

Figure 1. Measured arterial plasma thromboxane B_2 (TxB_2) and 6-keto prostaglandin $F_{1\alpha}$ (6-keto $PGF_{1\alpha}$) concentrations in control ($n = 6$) dogs (*solid lines*) with thoracotomy after bilateral cemented arthroplasty (Post-BCA) and in three ibuprofen (20 mg/kg) pretreated animals (*dashed lines*).

tion increased significantly above baseline (0.46 ± 0.10 ng/mL) to the 30-s and 1-min measurements (1.18 ± 0.66 and 1.17 ± 0.49 ng/mL, respectively) (Figure 1). The plasma TxB_2 concentration increased significantly from baseline (0.64 ± 0.15 ng/mL) in the same group to a mean value of 1.84 ± 1.25 and 1.31 ± 0.51 ng/mL at 30 and 60 s after BCA, respectively.

No increase from baseline plasma TxB_2 or 6-keto

Table 2. Arterial Plasma Concentration (mean ± SD) of Thromboxane B_2 and 6-Keto Prostaglandin $F_{1\alpha}$ in 12 Dogs With an Intact Chest Wall at Each Measurement Time

	Postreaming	1 min after BCA	5 min after BCA	15 min after BCA

BCA, bilateral cemented arthroplasty; TxB_2, thromboxane B_2; 6-keto $PGF_{1\alpha}$, 6-keto prostaglandin $F_{1\alpha}$; Control, control group ($n = 6$); Ibuprofen, ibuprofen (20 mg/kg)-pretreatment group ($n = 6$).

[a] Significant increase from the postreaming (baseline) values.

[b] Significant difference from the same measurement time in the control group.

$PGF_{1\alpha}$ was found at any measurement period in the ibuprofen-pretreated dogs ($n = 3$).

In the control group of animals with an intact chest wall (no thoracotomy), a significant increase in plasma TxB_2 and 6-keto $PGF_{1\alpha}$ was found within 5 min of BCA (Table 2). In ibuprofen-pretreated dogs without a thoracotomy, the arterial plasma concentration of TxB_2 and 6-keto $PGF_{1\alpha}$ was significantly lower (Table 2) than in the control group. The ibuprofen-pretreated dogs had no increase in plasma TxB_2 after BCA, whereas the control group had a significant increase at the 1-min measurement. Similarly, in the ibuprofen group, no increase from baseline plasma 6-keto $PGF_{1\alpha}$ concentration was found, whereas plasma 6-keto $PGF_{1\alpha}$ concentration in the control group increased at the 1-min measurement.

Quantitative Estimate of Fat Embolus

Quantitative morphometry of postmortem lung tissue compared the amount of fat embolized to the lung in the two groups of dogs without a previous thoracotomy. The volume proportion of lung occluded by fat was not significantly different between the control group (1.27% ± 0.29%) and the ibuprofen group (1.10% ± 0.25%). The size of vessels occluded by fat ranged from 7.0 to 14.3 μm, and no significant difference was found between groups in the size distribution of pulmonary vessels occluded by fat.

Discussion

This animal model (6) simulates hemodynamic changes during massive fat embolism, which is an infrequent clinical complication during cemented arthroplasty. To create this degree of fat and marrow embolism, we maximized the embolic load by performing bilateral, simultaneous arthroplasties using high-pressure prostheses with no lavage of the marrow cavity before BCA. This procedure creates reproducible, transient hemodynamic changes and pathological evidence of fat embolism similar to the fatal, massive embolism that has been reported in patients (5,7).

Fat and marrow embolism after BCA causes acute pulmonary hypertension (5) associated with transient hypotension (6). This study verifies our previous report (14) of a transient increase in plasma TxB_2 and 6-keto $PGF_{1\alpha}$ concentrations after BCA in this model (Figure 1, Table 2). Inhibiting the production of both vasoactive prostanoids by pretreating with ibuprofen (thus inhibiting the cyclooxygenase enzyme) was of interest for two reasons. First, many patients undergoing cemented arthroplasty receive long-term treatment with nonsteroidal antiinflammatory drugs; second, cyclooxygenase enzyme inhibition has attenuated pulmonary hypertension when particulate fat and marrow were infused from donor animals into recipients to create acute lung injury (13). In our study, significant pulmonary hypertension followed BCA in both groups, and ibuprofen was ineffective in reducing the PAP increase (Table 1). Similar results have been reported after air embolism (16).

If prostacyclin-induced vasodilation is a primary cause of systemic hypotension, ibuprofen pretreatment might reduce the decrease in BP. This study demonstrated that ibuprofen administered before BCA did not prevent the transient decrease in BP induced by cement and prosthesis insertion despite suppression of the prostanoid response (Table 2, Figure 1).

Quantitative morphometry of the lung demonstrated an equivalent "embolic load" in the control and ibuprofen-pretreated groups. The failure of ibuprofen to alter the hemodynamic changes was not due to a difference in either the number of emboli or the proportion of lung vasculature occluded by fat. Quantitative morphometry was not performed in dogs having a thoracotomy, because altered lung perfusion might change the intrapulmonary distribution of emboli and invalidate the quantitative estimate of embolic load. The use of a quantitative technique for comparison of embolic load is an important asset of the model, because clinical studies cannot quantify or compare the degree of fat embolism between groups. Clinical echocardiographic detection of embolic material (8,9) cannot precisely quantify the amount of fat in the lung. The surgical technique was standardized for all dogs; however, we must assume that the number of emboli in dogs with a thoracotomy was comparable to that in dogs with an intact chest wall, because similar hemodynamic and prostanoid changes were noted in both groups.

Because a stable hemodynamic state for reliable measurement of cardiac output often is not present in clinical practice, the cause of transient hypotension immediately after cement and prosthesis insertion has been difficult to evaluate (2). Pulmonary hypertension with fat embolism is a rare clinical event, making a detailed study of this problem difficult. Our data demonstrate that the decreased BP after BCA is associated with a transient decrease in cardiac output and that this reduced cardiac output is independent of prostaglandin production.

In these mongrel dogs, the decrease in cardiac output was transient, whereas significant pulmonary hypertension persisted. Because many patients having cemented arthroplasty are elderly and have cardiopulmonary disease, they may have less reserve to cope with a sudden increase in PAP and decrease in cardiac output. Moreover, the decrease in BP could be more protracted and more severe in high-risk patients than in these healthy dogs. The failure of ibuprofen to attenuate the decrease in BP in this model suggests that the transient increase in prostacyclin does not cause hypotension by vasodilation alone. Both LAP and RAP remained constant, suggesting that the acute reduction in aortic flow was not secondary to acute intravascular volume depletion.

Possible causes of hemodynamic instability after BCA include methylmethacrylate-induced vasodilation (17,18), reflex changes (19), generation of tissue thromboplastic products (1), prostaglandin release (14), and myocardial depression (20), as well as the mechanical effects of emboli. Our study does not address the specific role of cement in producing the hemodynamic changes after BCA, but it does document that a transient decrease in cardiac output accompanies the decreased BP and pulmonary hypertension. The failure of ibuprofen to alter this hemodynamic response suggests that either prostaglandin production is not a primary cause of hypotension or that the physiologic effects of the vasoconstrictor (thromboxane A_2) balance the effect of prostacyclin after cement and prosthesis insertion. This study also suggests that the pulmonary hypertension after fat embolism is not caused by thromboxane release. The decrease in cardiac output may result primarily from increased right ventricular afterload caused by elevated pulmonary vascular resistance. Alternatively, multiple factors, such as myocardial depression and systemic vasodilation, could interact with acute right ventricular dysfunction to cause the decrease in cardiac output.

In conclusion, this study suggests that pretreatment with ibuprofen before BCA does not reduce acute pulmonary hypertension or transient systemic hypotension associated with fat and marrow embolism during cemented arthroplasty. Also, these data show that the sustained pulmonary hypertension and transient decrease in BP are associated with a transiently reduced cardiac output.

We thank Kerry McClenaghan for preparation of the manuscript and J. C. Kay for technical assistance.

Fentanyl Does Not Alter the "Sleep" Plasma Concentration of Thiopental

Richard J. Telford, MB, ChB, FFARCS, Peter S. A. Glass, MB, ChB, FFA(SA),

Thiopental and fentanyl are commonly combined for induction of anesthesia. The effect of an analgesic concentration of fentanyl on the plasma concentration of thiopental to induce sleep was studied in 46 unpremedicated patients. As a measure of drug effect, sleep (the lack of response to open eyes to a verbal command) was used. Forty-six patients were randomized to receive thiopental infused to one of several predetermined plasma concentrations. Twenty-two of these patients also received a fentanyl infusion to a desired analgesic concentration of 1 ng/mL. Thiopental and fentanyl were infused by means of a pharmacokinetic model-driven infusion device (computer-assisted continuous infusion, CACI). Venous blood samples were taken from the contralateral antecubital fossa at 5 and 10 min after the start of the infusion. At 10 min, the patients' names were firmly spoken, and they were instructed to open their eyes. If they did not respond to this command, they were considered to be asleep. Only patients in whom the 5- and 10-min measured plasma concentrations of thiopental and fentanyl, respectively, were within ±30% of each other were used for the determination of the Cp_{50}(asleep), the plasma concentration at which 50% of the patients were asleep. The Cp_{50}(asleep) with and without fentanyl was calculated by logistic regression. The Cp_{50}(asleep) for patients in whom concentrations were maintained within ±30% for thiopental alone ($n = 17$) was 7.32 μg/mL (95% confidence interval, 5.53–10.95); for thiopental in the presence of fentanyl ($n = 18$ with a measured fentanyl concentration of 1.27 ± 0.5 ng/mL), this was 7.22 μg/mL (95% confidence interval, 4.83–10.15). There was no interaction between fentanyl (up to a concentration of 2.1 ng/mL) and the Cp_{50}(asleep) for thiopental. We conclude that fentanyl, at an analgesic concentration, has no effect on the hypnotic concentration of thiopental.

(Anesth Analg 1992;75:523–9)

Thiopental has been administered intravenously to induce anesthesia for >40 yr. During this time there have been many studies that have considered the amount of thiopental necessary for induction of anesthesia, the amount of thiopental necessary to abolish verbal counting, and the amount of thiopental necessary to abolish the response to surgical stimulation (1–5). These studies have used conventional dosing methodology, and their results may be misleading because of the influence of both pharmacokinetics and pharmacodynamics in characterizing the relationship among dose, plasma concentration, effect site concentration, and the response that is being observed (6). A single bolus dose results in a continuously changing plasma concentration and pharmacodynamic effect that are not linearly related; rather, they demonstrate hysteresis. Thus, when two drugs are administered as a bolus dose, the interaction observed is only applicable to the given dose of each drug and the time interval between drug administration and assessment of the pharmacodynamic response. Methods that ensure equilibration between the plasma concentration of a drug and the effect compartment accurately define the concentration-response relationship and therefore provide a time- and dose-independant evaluation of the pharmacodynamic interaction that may occur when two drugs are administered together. Fentanyl is commonly combined with thiopental for the induction of anesthesia. It is therefore important to establish the interaction of these two drugs in producing sleep (hypnosis). The purpose of this study was (a) to establish the concentration of thiopental necessary for hypnosis in 50% of patients [Cp_{50}(asleep)], and (b) to determine

whether an analgesic concentration of fentanyl alters the Cp_{50}(asleep) of thiopental.

Methods

After institutional review board approval of the protocol, written, informed consent was obtained from 46 patients. Patients <18 yr and those with a history of alcohol or drug abuse or presently receiving any hypnotic or opiate analgesics were excluded.

Patients were not premedicated before the study. When these unpremedicated patients arrived in the operating room, an intravenous catheter was inserted for fluid and drug administration. A second catheter was inserted in the contralateral antecubital vein to obtain blood samples for measurement of subsequent thiopental and fentanyl concentrations. Thiopental and fentanyl were infused with a pharmacokinetic model-driven drug-delivery device (computer-assisted continuous infusion, CACI) (7). This device uses pharmacokinetic simulations and infusion algorithms to calculate the infusion rate (every 9 s) required to immediately obtain and then maintain the set plasma concentration. The device then delivers this infusion rate by an infusion pump to the patient (8). The microcomputer was programmed with thiopental pharmacokinetic variables previously reported by Ghoneim and Van Hamme (9) and fentanyl kinetic variables reported by McClain and Hug (10).

Forty-six patients were randomly allocated to receive thiopental at a predicted plasma concentration of 5, 7.5, 10, 15, 20, or 25 μg/mL. In 22 patients, fentanyl was infused to a predicted (set) plasma concentration of 1 ng/mL. At 5 and 10 min after the initiation of the infusion, blood samples were drawn for subsequent measurement of drug concentration. At 5 and 10 min, patients' names were firmly spoken, and they were instructed to open their eyes. If patients did not respond to this command at 10 min, they were considered to be asleep.

The blood samples were immediately placed on ice, after which the plasma was separated and frozen at −70°C until assayed. The plasma concentration of fentanyl was measured by radioimmunoassay with fentanyl antisera and tritiated fentanyl (Fentanyl Radioimmunoassay kit, Janssen Biochemica, Belgium) (11). The lower limit of detection of the assay was 0.2 ng/mL. Total serum thiopental concentrations were measured with a high-performance liquid chromatographic assay sensitive to 100 ng/mL (12). The coefficient of variation of both assays was <10% over the concentration range measured. All assays were performed in duplicate. If the two measurements differed by >10%, the sample was reassayed.

To ensure that a stable plasma concentration of thiopental and fentanyl was maintained during the infusion, the 5- and 10-min samples were compared. Only pairs in which the 5-min sample was within ±30% of the 10-min sample were utilized for the calculation of Cp_{50}(asleep). Each 10-min sample was characterized as asleep/not asleep, and this plasma concentration was used in the determination of the concentration at which 50% of the patients were asleep Cp_{50}(asleep), which was calculated by logistic regression. The fit of the data to the model was accomplished with an iterative maximal likelihood technique (13). A Cp_{90}(asleep) (i.e., the plasma concentration at which 90% of the patients did not respond to a verbal stimulus) was similarly derived. The interaction of increasing fentanyl concentration on the Cp_{50}(asleep) of thiopental was also evaluated with a similar iterative maximal likelihood technique. The effect of age on the Cp_{50}(asleep) was also determined with age as a covariate in the model. For comparisons between groups, an unpaired Student's *t*-test was used. A P value <0.05 was considered significant. Fentanyl concentrations and demographic values were averaged, and the mean ±SD is reported.

Results

Forty-six patients completed the study. Of these, 24 received thiopental only, and 22 received thiopental plus fentanyl. The average age for patients receiving thiopental only was 32 ± 14 yr (range 18–71). The average age of patients receiving thiopental plus fentanyl was 41 ± 14 yr (range 18–64) ($P > 0.05$). The gender distribution in the two groups was 9 women and 15 men in the thiopental-only group and 8 women and 14 men in the combined thiopental-fentanyl group.

In 17 of 24 patients in the thiopental-only group, the 10-min sample was within ±30% of the 5-min sample. In the combined thiopental-fentanyl group, 18 of 22 patients had both fentanyl and thiopental 10-min concentrations within ±30% of the 5-min sample. The 5- and 10-min concentrations for all patients are illustrated in Figure 1. Only one patient was assessed as asleep at 5 min and awake at 10 min. In this patient, the thiopental concentration at 5 min was 7.6 μg/mL and at 10 min 5.5 μg/mL. Two patients were awake at 5 min (thiopental plasma concentration 11 and 7.5 μg/mL) and asleep at 10 min (thiopental plasma concentration 11.7 and 6.3 μg/mL).

In those patients meeting the criteria of maintaining the 5- and 10-min measured concentrations of thiopental and fentanyl within ±30%, the average measured concentration of fentanyl at 10 min was 1.27 ± 0.5 ng/mL (range 0.35–2.1). Because the fentanyl concentration was not exactly the same in each

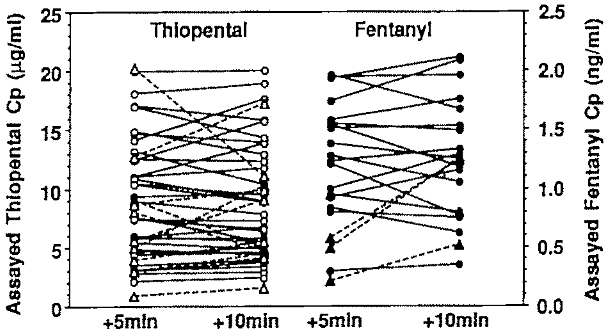

Figure 1. Measured plasma concentrations (Cp) of thiopental and fentanyl in 46 patients at 5 and 10 min after the start of an infusion intended to maintain a constant concentration of either or both drugs. *Solid line,* patients (n = 24) in whom the 5- and 10-min samples were within ±30%; *dashed line,* patients (n = 22) in whom the 5- and 10-min samples were not within ±30% and were subsequently excluded from the calculation of the Cp_{50}(asleep).

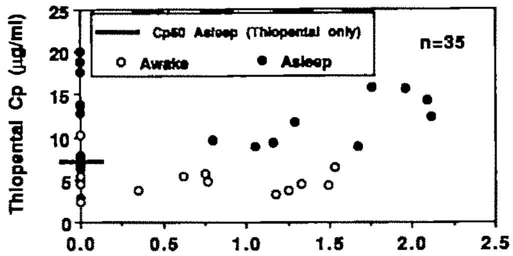

Figure 2. Thiopental and fentanyl plasma concentrations (Cp) at which patients (n = 35) were either awake or asleep (lack of response to open eyes to a verbal command) are plotted. No interaction between increasing fentanyl concentration (0–2.1 ng/mL) and the thiopental Cp_{50}(asleep) could be demonstrated.

patient, the thiopental versus fentanyl concentrations for patients asleep/not asleep are presented in Figure 2. Figure 2 demonstrates the lack of effect of increasing fentanyl concentration on the thiopental Cp_{50}(asleep). Analysis of the data showed no interaction of increasing fentanyl concentration (over the range 0–2.1 ng) with the thiopental Cp_{50}(asleep) ($P > 0.5$). Thus, all patients receiving fentanyl were grouped together. The Cp_{50}(asleep) (Table 1) for thiopental alone was 7.32 µg/mL (95% confidence interval, 5.53–10.95) (Figure 3), and in patients receiving fentanyl, the Cp_{50}(asleep) for thiopental was 7.22 µg/mL (95% confidence interval, 4.83–10.16) (Figure 4). There was no difference between the thiopental alone Cp_{50}(asleep) and the combined thiopental-fentanyl Cp_{50}(asleep) ($P > 0.5$). Because the Cp_{50}(asleep) for thiopental was not altered by the presence of fentanyl, all patients in whom the plasma concentration was maintained within ±30% were combined, and a Cp_{50}(asleep) value for this population was calculated (Table 1). For the 35 patients (age range 18–71 yr) included in the analysis of the Cp_{50}(asleep), age was neither a significant predictor of response nor a significant cofactor within the model ($P > 0.5$).

Table 1. Cp_{50}(asleep) and Cp_{90}(asleep) Values in 46 Patients

	Thiopental Cp_{50}(asleep) (µg/mL [95% CI])	Thiopental Cp_{90}(asleep) (µg/mL [95% CI])
Thiopental only, 5- and 10-min samples within ±30% (n = 17)	7.3 (5.5–10.9)	9.9 (7.8–27.1)
Thiopental plus fentanyl, 5- and 10-min samples within ±30% (n = 18)	7.2 (4.8–10.2)	9.8 (7.6–22.5)
Thiopental and thiopental plus fentanyl, 5- and 10-min samples within ±30% (n = 35)	7.3 (5.8–9.4)	9.8 (8.1–22.6)

Cp_{50}(asleep), thiopental concentration at which 50% of the patients were asleep, as assessed by a lack of response to their name being called; Cp_{90}(asleep), thiopental concentration at which 90% of patients were similarly assessed as asleep; CI, confidence interval.

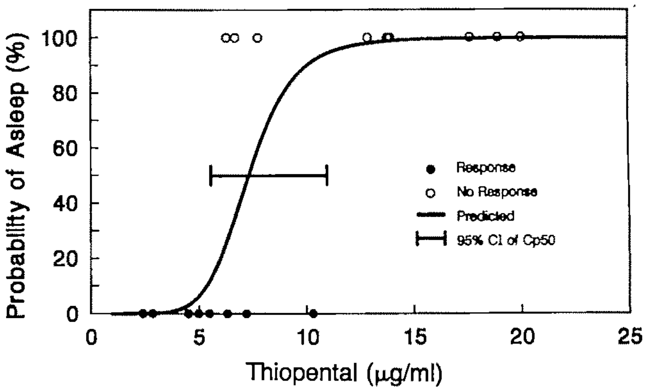

Figure 3. Thiopental plasma concentration at which patients (n = 17) were either awake or asleep (lack of response to open eyes to a verbal command) after 10 min of an infusion of thiopental maintained at a constant concentration. The thiopental plasma concentration at which there is a 50% probability of a patient not responding to a verbal command (Cp50) is 7.35 µg/mL (95% confidence interval, 5.5–10.9).

Discussion

This study established the hypnotic concentration of thiopental as 7.3 µg/mL (95% confidence interval, 5.5–10.9), and this was unaltered by an analgesic concentration of fentanyl up to 2.1 ng/mL.

Anesthesia commonly requires the administration of more than a single drug. For the inhaled anes-

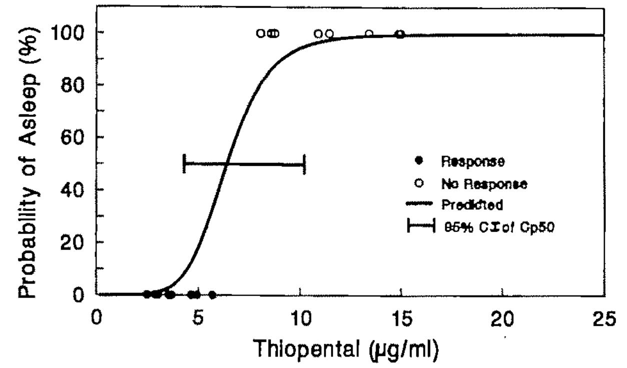

Figure 4. Thiopental plasma concentration at which patients (*n* = 18) were either awake or asleep (lack of response to open eyes to a verbal command) after a 10-min infusion of thiopental and fentanyl maintained at a constant concentration. The fentanyl concentration was maintained at 1.27 ng/mL (SD ±0.5). In the presence of this concentration of fentanyl, the thiopental plasma concentration at which there is a 50% probability of a patient not responding to a verbal command (Cp50) is 7.2 µg/mL (95% confidence interval, 4.8–10.2).

thetics, MAC (minimum alveolar concentration necessary to prevent a somatic response to skin incision in 50% of patients) has provided a measure of potency and has thus allowed the drug interaction of these anesthetics to be clearly defined (14). For intravenous anesthetics, potency is generally defined by the dose-response relationship. The relationship between dose and response can be misleading owing to the complex and time-varying influence of pharmacokinetics and pharmacodynamics (6).

Most previously published work with thiopental has used conventional dosing methodology (1–5,15,16) rather than drug concentration to study drug effect and drug interaction. There may be differences in pharmacokinetics of thiopental (especially related to age) so that the same dose of thiopental may result in markedly different plasma concentrations in different patients (17). Second, variables such as hysteresis affect the relationship between measured drug concentration and concentration at the effect site, therefore altering the relationship between drug concentration measured in plasma and the intensity of the effect produced (6,18). Ideally, the concentration at the effect site is needed to characterize the concentration-response relationship. It is usually not possible to measure the concentration of a drug at the site of action. Both thiopental (6) and fentanyl (18) result in hysteresis of their concentration-effect relationship. Thus, any study in which the plasma concentration is constantly varying (e.g., bolus dose or rapid infusions) will result in a false interpretation of the plasma concentration-effect relationship, unless hysteresis is accounted for by complex mathematical modeling.

Recently, the IC_{50} (concentration required to produce one-half of the maximal EEG, which is derived from an inhibitory Emax model relating the spectral edge of the EEG to the measured arterial concentration of thiopental) has been proposed as a measure of potency for thiopental (6,17,18). The IC_{50}, because it accounts for both pharmacokinetic and pharmacodynamic effects, is an appropriate measure of potency. Different drugs produce different effects on the EEG, and therefore the IC_{50} may not be the ideal measure of potency when trying to establish the interaction between two different drugs. Hypnosis is a common and easily definable clinical end point. It therefore is a convenient measure of effect.

When using a single measure of effect to define the concentration-response relationship, it is still necessary to account for pharmacokinetic and pharmacodynamic influences. This can be done by maintaining the concentration constant for a sufficient period to provide equilibration of drug plasma concentration and effect site concentration. Under steady concentration conditions, the drug concentration at the site of action will, after a set delay (as determined by the drug's keo, where $t_{1/2}$ keo is the half-life for equilibration between plasma concentration and drug effect), be proportional to the plasma concentration and thus allow the determination of a true concentration-effect relationship. To ensure adequate equilibration between plasma concentration and the effect site, the desired plasma concentration was maintained for 10 min. With the keo values determined for thiopental (6) and fentanyl (18), at 10 min the equilibration between plasma and brain concentration would be predicted to be 100% for thiopental and 75% complete for fentanyl. Under these conditions, we determined that the plasma concentration of thiopental necessary to provide a loss of response to a verbal command (i.e., hypnosis) in 50% of our patients was 7.3 µg/mL in the absence or presence of fentanyl (0–2.1 ng/mL). The Cp_{90}(asleep) of thiopental was 9.8 µg/mL. With the development of commercially available CACI devices, the Cp_{90}(asleep) may become a clinically useful value, because it represents the thiopental concentration required to provide loss of consciousness in 90% of patients.

To provide a steady plasma concentration, we used a pharmacokinetic model-driven infusion device that permits drugs to be infused to a desired plasma concentration. Pharmacokinetics vary from patient to patient, and thus any infusion scheme cannot precisely obtain and maintain a desired concentration. From our previous work with CACI, we have found that when using a pharmacokinetic set that tends to neither over nor underpredict the desired concentration, the variation of the predicted to measured concentration in most patients is ±30%. Ideally, the desired concentration should be maintained exactly, but with present technology this is impossible. We therefore had to choose a degree of variability that was both obtainable yet was unlikely to alter the accuracy of calculating the Cp_{50}(asleep). We knew that we could achieve a steady concentration within ±30% in the majority of our patients, and thus we accepted this degree of variability for calculation of the Cp_{50}(asleep) and Cp_{90}(asleep). From our results it would appear that this degree of variability in concentration over the 10-min infusion was adequate to describe the pharmacokinetic dynamic relationship with thiopental. This is confirmed by the one patient who was asleep at 5 min with a thiopental plasma concentration of 7.5 μg/mL and was awake (as would be predicted by the model) at a concentration of 5.6 μg/mL at 10 min.

There are several studies that have investigated either the hypnotic concentration of thiopental or the interaction of thiopental and fentanyl in providing hypnosis. Becker (3) administered a bolus dose of 1.5 mg/kg, followed by a rapid infusion of 1.5 $mg \cdot kg^{-1} \cdot h^{-1}$ of thiopental, and determined the concentration of thiopental to prevent a response to a painful stimulus as 42.2 ± 2.8 μg/mL. The thiopental Cp_{50}(asleep) defined in our study is much lower than that obtained by Becker both because his endpoint was different (loss of response to a painful stimulus), and he did not account for hysteresis. There are several studies that, although not defining the Cp_{50}(asleep), do support the value that we obtained. The plasma concentration of thiopental on awakening after a thiopental infusion was previously reported as 5.9 ± 1.1 μg/mL (19) and 8 μg/mL (20). Both values are very similar to the concentration that we determined to just produce hypnosis in 50% of patients. When a thiopental infusion was used to provide sedation/sleep in patients in an intensive care unit, the measured thiopental plasma concentration at 24–36 h after initiating the infusion was 8.78 μg/mL (21). There have also been several studies in which the EEG and thiopental concentrations have been measured (6,16,22,23). Thiopental produces a biphasic effect on the EEG amplitude, with an initial increase followed by a decrease in amplitude. Early stage 2 of the EEG after thiopental administration is associated with loss of consciousness (6,23). Buhrer et al. (23) found that stage 2 was obtained with a thiopental concentration of 10 μg/mL. Hudson et al. (6) defined the IC_{50} of thiopental as 16 μg/mL. Although this value is higher than the concentration that we determined to provide hypnosis, the EEG endpoint used to define this concentration is greater than that expected to just provide loss of consciousness. Thus, in studies in which a steady concentration was maintained and hysteresis was accounted for, the plasma concentration of thiopental required to provide hypnosis is in general agreement with the value that we have defined as the thiopental Cp_{50}(asleep).

We used venous blood samples for our assessment of the Cp_{50}(asleep). Venous blood concentrations may vary according to the sampling site, and hysteresis with thiopental venous concentrations may be less than that with arterial concentrations (6). Although for both thiopental (22) and fentanyl (7) after a 10-min infusion, venous samples obtained from the arm closely approximate arterial concentrations, it may be preferable to use arterial rather than venous blood samples to relate measured drug concentration to effect.

The second portion of our study investigated the drug interaction of an analgesic concentration of fentanyl on the thiopental Cp_{50}(asleep). The interaction of thiopental and fentanyl has previously been studied (4,5,15,16); however, these studies have investigated this interaction with combinations of bolus doses. We chose to infuse fentanyl to a predicted plasma concentration of 1 ng/mL, because previous studies have suggested that plasma levels of this magnitude are sufficient to provide satisfactory postoperative analgesia (24). Also, in studies determining the MAC reduction of either isoflurane (25) or desflurane (13) by fentanyl, reduction in MAC was very steep between a fentanyl concentration of 0 and 1 ng/mL. We were unable to demonstrate any significant change in the Cp_{50}(asleep) for thiopental in the presence of an analgesic concentration of fentanyl. This is in contrast to several other studies in which bolus doses of fentanyl decreased the induction dose of thiopental (4,5,15,16). The differences between our results and these studies may be due to differences in methodology. In addition, low doses of fentanyl (1.5 μg/kg) resulted in only a small decrease in the thiopental dose (13%) (5), whereas larger fentanyl doses (4 μg/kg) resulted in more pronounced decreases in thiopental requirements for the induction of anesthesia (15,16). Even a dose of 1.5 μg/kg will result in a peak plasma and effect compartment concentration that exceeds 2.0 ng/mL. Thus, a possible explanation for the differences in our findings compared with those of others is that the effects of fentanyl on reducing thiopental requirements to produce sleep are only evident at higher fentanyl concentrations. Certainly, the pharmacodynamic effects of fentanyl (e.g., respiratory depression and analgesia) occur over slightly different plasma concentration ranges, and the dose of fentanyl required to induce loss of consciousness is much higher than that required to produce analgesia. Becker (3), as in our study, found that a small but analgesic dose of meperidine (1.2 mg/kg) did not alter the concentration of thiopental to prevent a response to a painful stimulus. Thus, any interaction of fentanyl and thiopental appears to be minimal at low (analgesic) concentrations but may be additive or synergystic at higher concentrations of fentanyl.

The MAC (awake), the concentration at which 50% of patients respond to command, is not altered by opiates (26,27). This is in contrast to the decrease in MAC (concentration at which 50% of patients do not respond with purposeful movement to skin incision) produced by fentanyl concentrations between 0 and 2 ng/mL (13,25). Thus, although our study has shown a minimal interaction between low fentanyl concentrations and thiopental on hypnosis, this interaction may be markedly different if the endpoint measured is response to skin incision (cf. MAC).

Age has an important influence on the effect of drugs in producing anesthesia (14,17). The MAC of the potent inhaled anesthetics is clearly altered by age (14). Several studies have also demonstrated that the induction dose of thiopental is decreased with increasing age (1,17). This altered sensitivity to thiopental may be due to changes in either pharmacokinetics or pharmacodynamics that occur with increasing age. It was recently shown that the decrease in dose of thiopental is due to changes in the rapid intercompartmental clearance with increasing age rather than an alteration in brain sensitivity (17,28). Our study covered an age range of 18–71 yr, and we also found that age did not affect the determination of the Cp$_{50}$(asleep), thus confirming that the sensitivity of the brain to thiopental is unaltered by increasing age.

Utilization of a pharmacokinetic model-driven infusion system (e.g., CACI), programmed with average pharmocokinetic variables, enables a stable plasma concentration to be obtained. By knowing that hysteresis occurs and using the keo for the drug(s) under study, a constant relationship between plasma concentration and biophase concentration can be established, and the patient's response to a stimulus can be quantified. Thus, the potency of various intravenous anesthetics need no longer be compared in terms of dose; rather, they can be compared in terms of the plasma concentration required to produce or prevent an effect/response in 50% of the patients tested. It is customary to compare the potency of the various inhaled anesthetics in terms of their MAC values. This has greatly improved comparisons made among these anesthetics. The MAC has also enabled drug interactions to be clearly defined with regard to the potent inhaled anesthetics. The methodology used in this study is analogous to that used when determining the MAC for an inhaled anesthetic. The drug is infused over a given time period until a constant plasma and biophase (effect) level is obtained and the response to a given stimulus is measured. The determination of the Cp$_{50}$(asleep) will similarly enable accurate comparisons among the various intravenous anesthetics (and among the opiates) and will allow their interactions to be clearly defined.

Further studies using this methodology are required, first to elucidate the plasma concentration of thiopental at which there is no response to a surgical stimulus (Cp$_{50}$[surgical stimulus]) and second to examine the effects of higher plasma levels of fentanyl both on the Cp$_{50}$(asleep) and the Cp$_{50}$(surgical stimulus) for thiopental. There are also other intravenous drugs used to provide anesthesia, many of which have been reported to have a synergistic interaction when evaluated by their dose-response effects. Our results suggest that further work is required, using methodology similar to ours, to clearly characterize the interaction of the intravenous anesthetics.

In summary, we have used a computer-controlled continuous infusion device to define the Cp$_{50}$(asleep) for thiopental in unpremedicated subjects and demonstrated that fentanyl infused to an analgesic concentration has no effect on the hypnotic concentration of thiopental. This methodology may be extrapolated to elucidate the Cp$_{50}$(asleep) for all of the currently available intravenously administered drugs used to induce anesthesia and thus allow their potencies to be compared in the same way that MAC compares the potencies of the various inhaled anesthetics.

Effect of Intravenous Clonidine on the Dose of Thiopental Required to Induce Anesthesia

Kate Leslie, MBBS, Patricia H. Mooney, RN, and Brendan S. Silbert, FFARACS, FFARCS

Department of Anaesthesia, St. Vincent's Hospital, Melbourne, Victoria, Australia

---

A randomized, double-blind, controlled trial was conducted to investigate the influence of intravenous clonidine on thiopental dose requirements when used for induction of anesthesia and associated hemodynamic effects. Sixty ASA physical status I or II patients were randomly allocated to one of three treatment groups: normal saline solution (control, $n = 20$); clonidine (2.5 μg/kg, $n = 20$); or clonidine (5 μg/kg, $n = 20$). The test drug was administered 15 min before induction of anesthesia with intravenous thiopental. The dose of thiopental to produce loss of lash reflex was recorded as well as mean arterial blood pressure and heart rate at 3-min intervals up to induction of anesthesia and then at 1-min intervals for 5 min. Significant decreases in thiopental dose were observed in both groups receiving clonidine compared with the control group, but there was no significant difference between clonidine groups. With dosage calculated according to total body mass, the control group required 5.50 ± 1.15 mg/kg (mean ± SD) of thiopental, whereas those who received 2.5 μg/kg of clonidine required 4.15 ± 1.46 mg/kg of thiopental (a reduction of 25%), and those who received 5.0 μg/kg of clonidine required 3.48 ± 1.06 mg/kg of thiopental (a reduction of 37%). When thiopental dose was adjusted for lean body mass, similar reductions were obtained. Clonidine, in both doses, produced more sedation than control, and the 2.5-mg/kg dose produced less sedation than the larger dose. Mean arterial blood pressure was lower in the groups receiving clonidine. There were no significant differences in heart rate among the three groups. If intravenous clonidine is to be used as an adjunct to general anesthesia, appropriate adjustments to the dosage of intravenous thiopental will be required.

(Anesth Analg 1992;75:530–5)

Clonidine is an α_2-adrenergic receptor agonist that acts centrally to decrease sympathetic outflow. The use of clonidine as an antihypertensive is associated with sedation in the acute clinical situation, and because similar drugs are used as anesthetics in veterinary practice (1), much interest has focused on the potential anesthetic properties of this drug in humans. Orally administered clonidine decreases anesthetic requirements for fentanyl (2), droperidol (3), and isoflurane (4), but there is limited information on its effects when given by the more rapid and reliable intravenous route.

Several drugs, such as fentanyl (5) or midazolam (6,7), are often administered intravenously in conjunction with thiopental to decrease thiopental dosage requirements, although data on hemodynamic stability are limited. The pharmacodynamic profile of clonidine suggests that it may also be suitable for this purpose, especially because it produces minimal respiratory depression (8) and possesses analgesic properties (9,10). There are many other potentially useful effects of clonidine during anesthesia, including sympatholysis, as evidenced by attenuation of the pressor response to intubation (11), amelioration of postoperative hypertension and tachycardia (12), and decreased circulating levels of norepinephrine (3) and β-endorphin (13). In addition, intraoperative hemodynamic stability in patients undergoing coronary bypass surgery has been reported (14).

To examine (a) whether intravenous clonidine could be safely administered before induction of anesthesia and (b) the effect on thiopental requirements, we conducted a randomized, double-blind, controlled trial comparing two doses of clonidine (2.5 and 5 μg/kg) administered intravenously 15 min before induction of anesthesia. We also documented the effects of clonidine and the combination of clonidine and thiopental on mean arterial blood pressure (MABP) and heart rate (HR).

Methods

Sixty patients aged 18–50 yr of ASA physical status I or II who presented for elective surgery were accepted for this study. Patients receiving sedatives, opiates, or medication affecting the cardiovascular system were excluded, as were those with untreated hypertension (systolic blood pressure >180 mm Hg) and obesity (>50% fat) likely to cause difficulty with mask ventilation. The study was approved by the Hospital Ethics Committee, and all patients gave informed consent.

The total body mass (TBM) of each patient was measured preoperatively. Lean body mass (LBM) was then determined using TBM (kg), height (cm), and girth at the umbilicus (cm), as described previously by Wolfsohn and Joshi (15):

$$\% \text{ Fat} = 90 - (\text{Height} - \text{Girth})/0.79;$$

$$\text{LBM} = [(100 - \% \text{ Fat})/100] \times \text{TBM}.$$

No premedication was administered. On arrival in the operating suite, an intravenous infusion of lactated Ringer's solution was begun. Routine monitoring, including a Dinamap (Critikon) for noninvasive measurement of blood pressure, was used. Random-number tables were used to allocate the 60 patients to three groups of equal size. The control group received normal saline solution (10 mL); the two study groups received clonidine (Catapress, Boehringer) (2.5 or 5.0 μg/kg) diluted in 10 mL of normal saline solution. Drugs were prepared independently in a 10-mL syringe marked "study drug," and the administering anesthesiologist remained unaware of the identity of the drug.

Baseline arterial blood pressure, HR, and oxygen saturation were recorded. The "study drug" was then administered intravenously over 60 s. The electrocardiograph was continuously observed, and oxygen saturation, MABP, and HR were monitored and recorded every 3 min for 15 min. At 15 min, just before administration of thiopental, sedation was graded 0–5 (0 = awake, anxious; 1 = awake, calm; 2 = drowsy, eyes open; 3 = mild sedation, eyes closed, responds to verbal command; 4 = moderate sedation, unresponsive to verbal command, responds to light touch; 5 = profound sedation, unresponsive) (16).

After 15 min, 2.5% thiopental was injected at a rate of 50 mg every 15 s until loss of the eyelash reflex occurred. The patient was then allowed to breathe 100% oxygen spontaneously for 5 min while the MABP, HR, and oxygen saturation were measured every minute. Thereafter, the anesthetic was conducted as indicated for the surgery. At the end of each case, the anesthetic records were reviewed, and any untoward effects were noted.

Table 1. Demographic Data of 60 Patients Undergoing Elective Surgery

	Control group (n = 20)	Clonidine group (2.5 μg/kg) (n = 20)	Clonidine group (5.0 μg/kg) (n = 20)
M/F	11/9	10/10	9/11
Age (yr)	27.1 ± 7.7	28.4 ± 6.4	31.0 ± 8.5
TBM (kg)	70.6 ± 11.3	68.9 ± 10.0	71.8 ± 15.0
LBM (kg)	55.5 ± 9.2	55.2 ± 9.1	55.3 ± 13.4
% Fat	19.3 ± 10.5	19.7 ± 5.6	22.6 ± 11.4

M/F, male/female; TBM, total body mass; LBM, lean body mass.
Values are mean ± SD.

SuperANOVA (Abacus Concepts, Berkley, Calif.) and BMDP (Statistical Software, Berkley, Calif.) were used for statistical analyses. The level of significance was set at $P < 0.05$. All data are expressed as mean ± SEM, except dosage of thiopental, which is expressed as mean ± SD. Demographic data were analyzed with analysis of variance. Because of the sequential nature of the observations, hemodynamic data were analyzed with a repeated measures analysis of variance (17). Data obtained in the 15 min after clonidine administration were analyzed separately from data obtained after induction of anesthesia. Sedation scores were compared with the Mann-Whitney U-test.

Results

There were no significant differences among the three treatment groups with regard to mean age, gender, TBM, LBM, and percent body fat (Table 1).

Intravenous clonidine significantly decreased the dose of thiopental required to produce loss of eyelash reflex compared with control, whether dosage was calculated according to TBM or LBM (Figure 1). Control patients required 5.50 ± 1.15 mg/kg TBM (mean ± SD) or 7.06 ± 1.72 mg/kg LBM. A clonidine dose of 2.5 mg/kg reduced the thiopental requirement by 25% (4.15 ± 1.46 mg/kg TBM and 5.21 ± 1.51 mg/kg LBM). A clonidine dose of 5.0 mg/kg reduced the thiopental requirement by 37% (3.48 ± 1.06 mg/kg TBM) and 36% (4.55 ± 1.31 mg/kg LBM). There was no significant difference between the two clonidine groups in terms of thiopental dose. With 40 subjects, 80% power ($\beta = 0.20$) would detect a change >0.8 mg/kg. Because we believe that clinically significant changes are greater than this, the power was more than adequate for this analysis.

Mean sedation scores at 15 min, just before thiopental administration, were 0.85 ± 0.15 for the control group, 2.0 ± 0.20 for the 2.5-mg/kg group, and 2.55 ± 0.17 for the 5.0-mg/kg group. There was a highly significant difference between the control

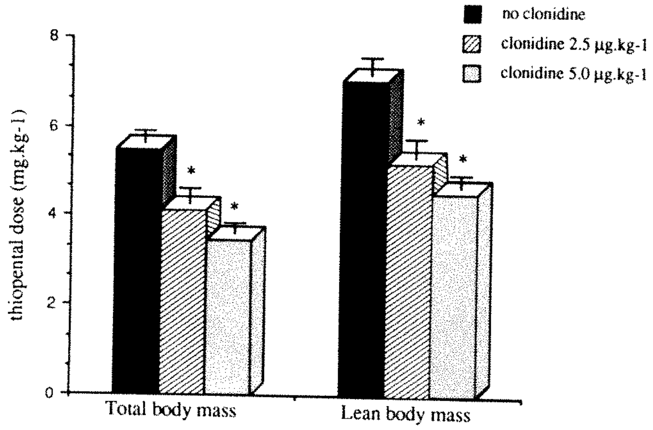

Figure 1. The effect of intravenous clonidine on the induction dose requirement of thiopental with thiopental dosage based on total body mass and lean body mass (mean ± SEM). $^*P < 0.05$ compared with no-clonidine group.

group and each of the clonidine groups ($P = 0.0001$ for both comparisons); however, the difference between the two clonidine groups only just reached statistical significance ($P = 0.0478$).

There was no significant difference among the three groups in baseline MABP or HR. The relationship between MABP and time for the three groups is shown in Figure 2. The MABP decreased significantly with time in all three groups until induction with thiopental. After induction of anesthesia, MABP continued to decrease in each group, but this was not significant in any group. Patients receiving clonidine had significantly lower MABP than control patients at 3, 6, 9, 12, and 15 min after administration. After induction, no statistically significant differences were found among the three groups. No difference was demonstrated between the two doses of clonidine at any time either before or after induction.

Figure 3 shows the relationship between HR and time for the three groups. The interaction between HR and time was statistically significant; HR decreased in all groups until just before induction. The administration of 2.5 or 5.0 µg/kg of clonidine did not have a significant effect on HR at any time.

Discussion

Intravenous clonidine administered before induction of anesthesia effectively decreased thiopental requirements and provided sedation. No patient complained of an unpleasant experience, and there were no adverse side effects. Our results confirm other work demonstrating the anesthetic-sparing effect of clonidine (2–4). Although this effect may be due solely to a decrease in central noradrenergic transmission, evidence is now accumulating to the effect that the α_2-receptor itself may mediate an anesthetic response (18). In animals, an intravenous dose of 5.0 mg/kg reduced the minimal anesthetic concentration (MAC) of halothane in the dog by 42% (19) and, in the rat, a dose of 10 mg/kg reduced MAC by 32% (20).

There are limited data on the use of the intravenous preparation as an anesthetic supplement in humans. It has been shown recently by Carabine et al. (11) that 0.625 and 1.25 µg/kg of clonidine attenuates the response to endotracheal intubation and decreases thiopental requirements (15% and 28%, respectively) while producing no significant changes in MABP or HR in the 15 min after its administration. Although we used larger doses of clonidine, we observed a smaller decrease in thiopental dose requirement for the 2.5-µg/kg group (25%) than the 1.25-mg/kg group (28%) of the Carabine et al. (11) study. This was probably due to the temazepam premedication used in the latter study.

Previous studies have shown that the administration of thiopental on the basis of LBM results in much less variation in response than when TBM is used to calculate dosage (15). In this study, the reduction in thiopental requirement was similar whether TBM or LBM was used. This may have resulted from the patients having relatively low body fat with little variation within each group.

The decreased MABP in the clonidine groups raises the possibility that this may have unblinded the study and introduced observer bias. However, because the changes in hemodynamic variables in all groups were minimal in the time leading up to thiopental administration, and because of the manner in which the study was conducted, we remain confident that no such bias was introduced.

It appears that increasing doses of clonidine produce a progressive reduction in thiopental requirements. This is most certainly a pharmacodynamic interaction, because we are unaware that clonidine has any effect on thiopental redistribution. Whether clonidine has the capacity to further reduce anesthetic requirements in humans when given in doses >5 mg/kg remains to be discovered. It has been shown that sedation and plasma concentration of clonidine are positively correlated up to 1.5–2.0 ng/mL, but that above this, the maximal level of sedation persists unchanged (21). It may be that the dose-response curve of clonidine reaches a plateau at high doses.

Investigating the optimal dose of clonidine must be done with caution because clonidine has significant hypotensive properties. Fortunately, the hypotensive effect of clonidine in normotensive patients appears to be less than in patients with hypertension (21). The normotensive patients studied here demonstrated significant but clinically tolerable decreases in

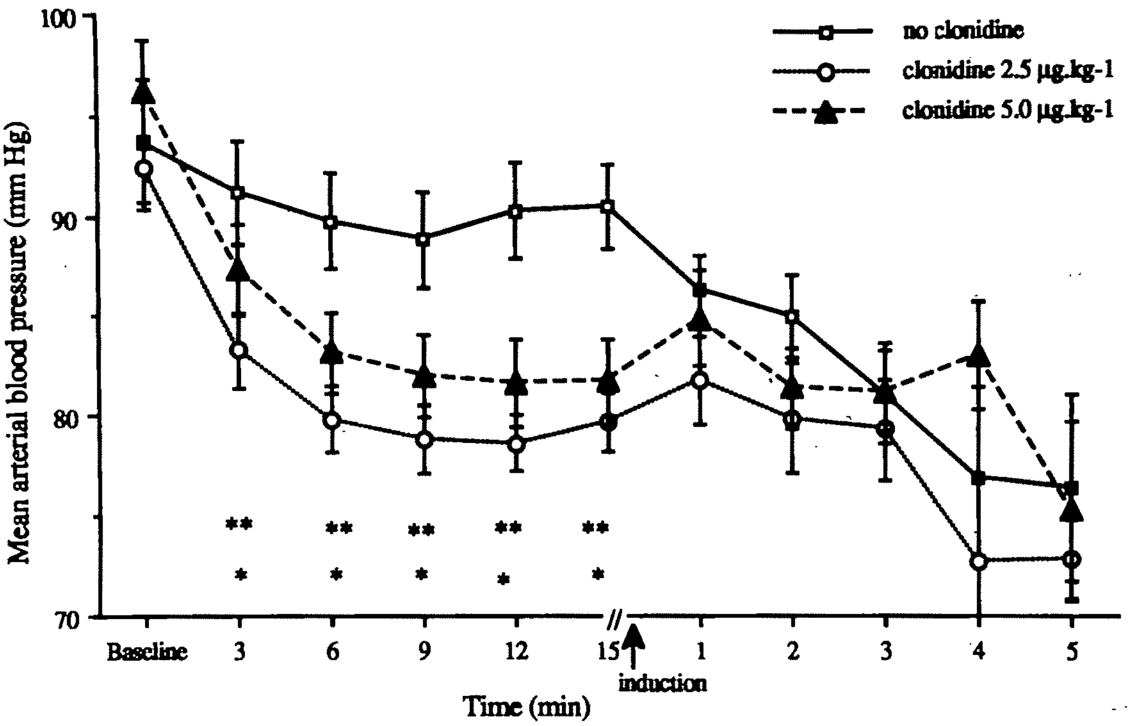

Figure 2. Relationship between mean arterial blood pressure and time. *$P < 0.05$ when 2.5 μg/kg clonidine group was compared with no-clonidine group. **$P < 0.05$ when 5.0 mg/kg clonidine group was compared with no-clonidine group.

MABP, and there was no difference among the three groups in the hemodynamic response to thiopental administration. Of importance, there was no pronounced decrease in MABP caused by the combination of the two drugs, although the hypotensive effects of clonidine may well outlast those of thiopental.

The two doses of clonidine used in this study did not differ significantly in their hypotensive effects. This may be explained by the fact that at higher blood levels of clonidine, peripheral α-receptor stimulation is more prominent than at lower levels and causes an increase in arterial blood pressure owing to a rise in systemic vascular resistance (1). This may be due to partial agonist activity at postsynaptic peripheral α_1- or α_2-receptors. The central α_2-receptor effect, which is responsible for the long-term antihypertensive effects of clonidine, occurs at lower blood levels. We demonstrated no significant effect of clonidine on HR in our healthy subjects. A relative bradycardia has been demonstrated by other workers, but the magnitude of this is usually small (22).

Although it would have been desirable to study hemodynamic variables throughout the intraoperative period, the surgery for which our patient population presented was too diverse to allow a standard anesthetic regime and thus continue the study intraoperatively. Review of the anesthetic records did, however, reveal the occurrence of hypotension and bradycardia. In the control group, there were 7 of 20 patients in whom the systolic blood pressure decreased below 100 mm Hg; in 5 of 20 patients, the HR was recorded as <60 beats/min. None of these patients received treatment. In contrast, 13 of 20 patients in the 2.5-μg/kg clonidine group and 15 of 20 patients in the 5.0-μg/kg clonidine group recorded systolic blood pressure <100 mm Hg during the intraoperative period, and 7 of 20 and 11 of 20, respectively, recorded HR as <60 beats/min. Four patients in the low-dose group and three patients in the larger dose group received treatment for either hypotension or bradycardia. In no case was any adverse outcome recorded.

Many factors may lead to circulatory instability in the intraoperative period. The addition of nitrous oxide, volatile anesthetics, and opiates, movement of the patient from the anesthetic to the operating room, and the effects of surgery may all have contributed. It may be necessary to alter the management of anesthesia after the use of clonidine in light of the intrinsic anesthetic properties of this drug. Alternatively, clonidine may have been the cause of hypotension on its own, because the maximal hypotensive effect may not occur until approximately 90 min after injection (22). The design of this study did not allow an evaluation of the timing of the maximal point of cardiovascular effects of intravenous clonidine.

Clonidine (2.5 mg/kg) proved to be an effective

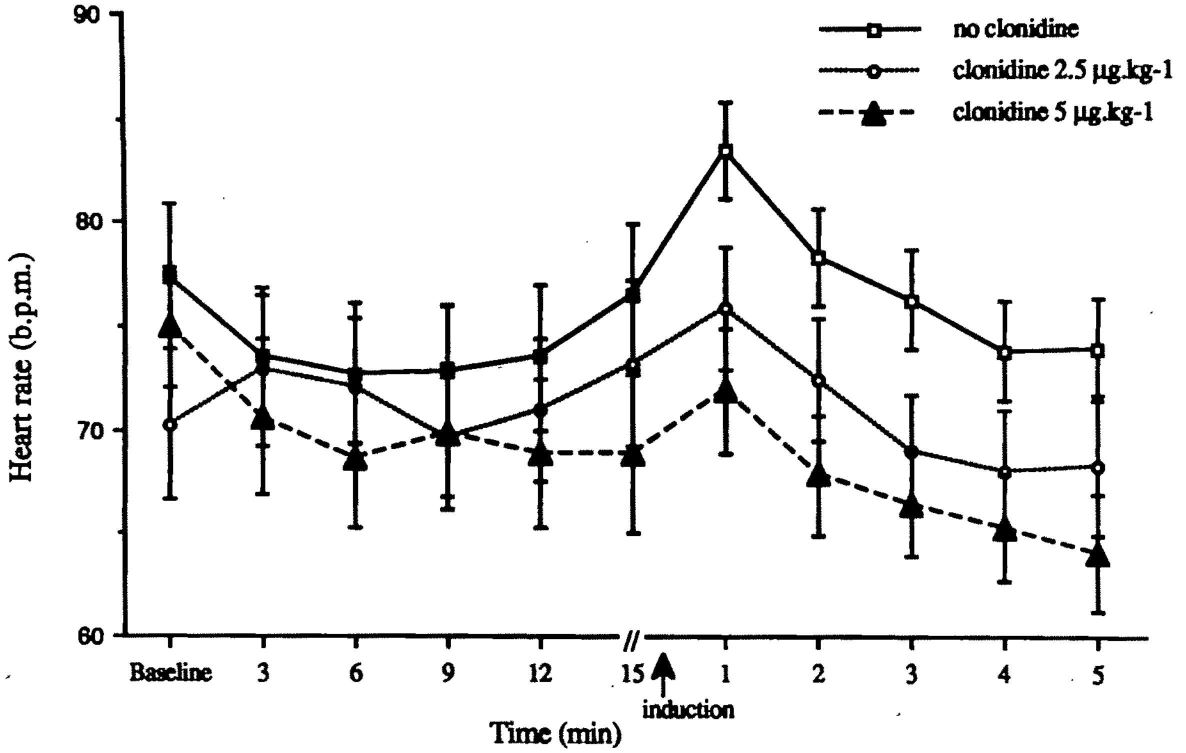

Figure 3. Relationship between heart rate and time. No significant differences between groups. b.p.m., beats/min.

sedative, and only a small incremental effect was gained by increasing the dose. This result is consistent with the thiopental requirements and hemodynamic effects, which also displayed modest changes at the larger dose.

In conclusion, intravenous clonidine administered before administration of thiopental diminishes anesthetic requirements and provides sedation. Significant decreases in MABP may occur with little change in HR. Although there is no major early hemodynamic instability, hypotension and bradycardia may occur later during the intraoperative course. Our results suggest that limited advantage may be gained by increasing the dose of clonidine to 5.0 mg/kg. Intravenous clonidine may be safely administered before induction of anesthesia, allowing further evaluation of the many useful effects during general anesthesia.

We gratefully acknowledge the contribution of Dr. John Santamaria in the conduct of the statistical analyses.

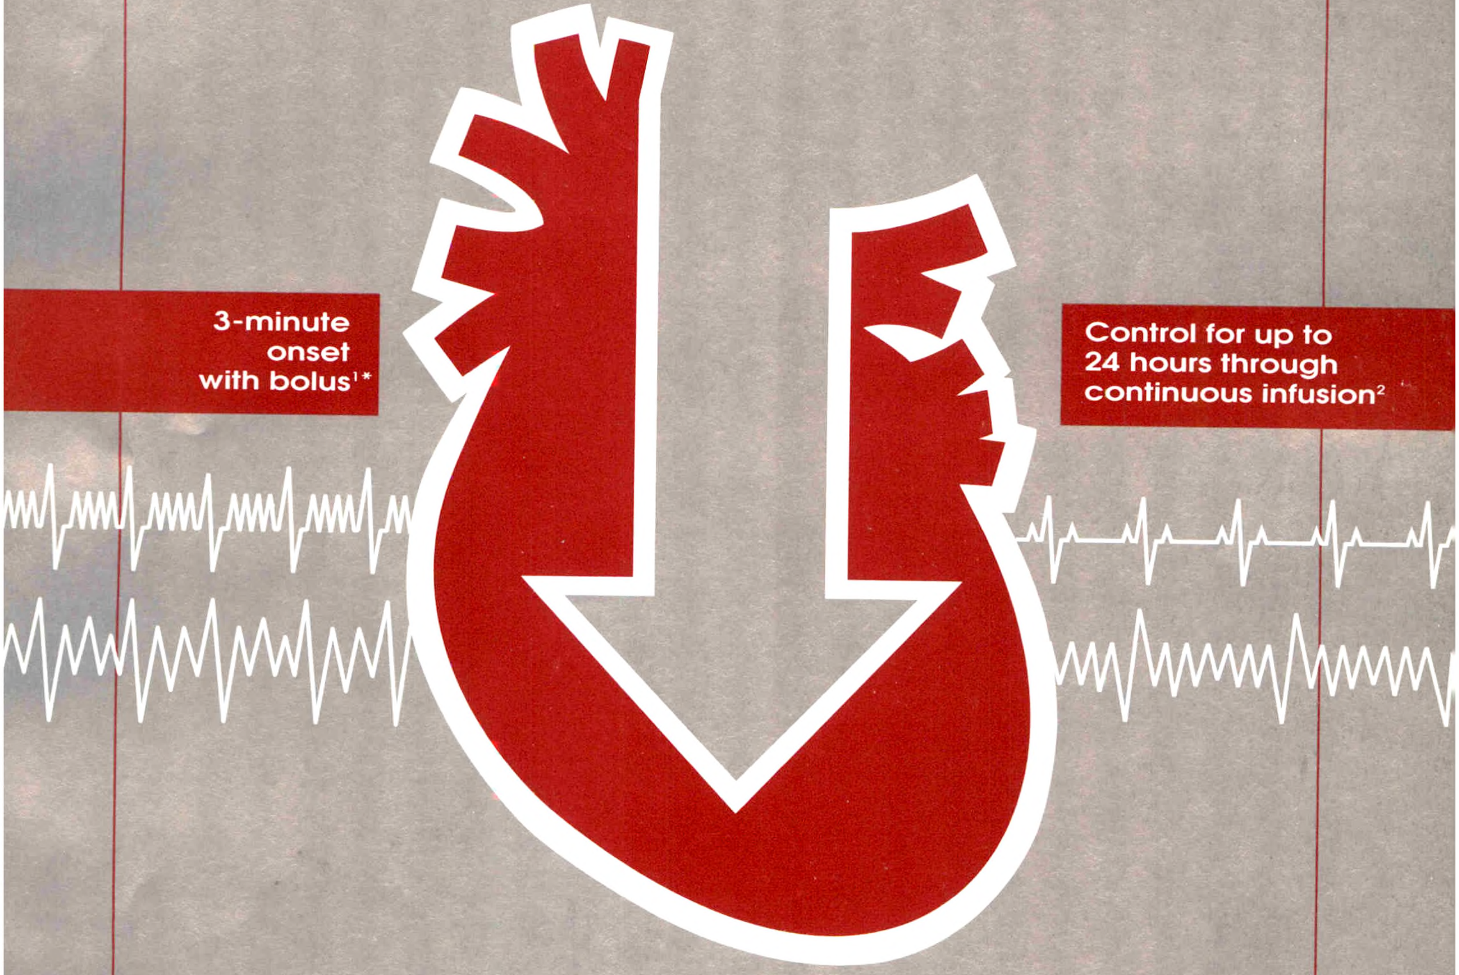
Now for heart rate control during atrial fibrillation and flutter

CARDIZEM® Injectable
(diltiazem hydrochloride)
BOLUS INFUSION
5 mg/mL



3-minute onset with bolus[1]*

Control for up to 24 hours through continuous infusion[2]

Heart rate control that is

FAST, SAFE, AND CONTINUOUS[1,2†]

Cardizem Injectable is indicated for temporary control of rapid ventricular rate during atrial fibrillation and flutter; rarely converts to normal sinus rhythm; should be used with continuous monitoring of ECG and blood pressure to avoid hypotension or bradycardia. Infusion rate/dose should be regulated accordingly. A defibrillator and emergency equipment should be readily available.

*Symptomatic hypotension (3.2%) or flushing (1.7%) occurs most often during or immediately following bolus injection. †Contraindications: atrial fibrillation and flutter patients with WPW or short PR syndrome; sick sinus syndrome or second- or third-degree AV block, except with a functioning pacemaker; severe hypotension or shock; hypersensitivity; recent IV beta-blockers; ventricular tachycardia.

Please see the brief summary of prescribing information on an adjacent page.

(diltiazem hydrochloride)

BOLUS INFUSION

CONVENIENT DOSAGE

1 Beginning treatment as

BOLUS: 0.25 mg/kg actual body weight **over 2 minutes**

20 mg average patient

2 If response is inadequate, wait 15 minutes

BOLUS: 0.35 mg/kg actual body weight **over 2 minutes**

25 mg average patient

3 Treatment as

INFUSION:

10* to 15 mg/hr

*5 mg/hr may be appropriate starting infusion for some patients.

BRIEF SUMMARY

CARDIZEM® Injectable

(diltiazem hydrochloride)

INDICATIONS AND USAGE

CARDIZEM Injectable (diltiazem hydrochloride) is indicated for the following:

1. ***Atrial Fibrillation or Atrial Flutter.*** Temporary control of rapid ventricular rate in atrial fibrillation or atrial flutter. It should not be used in patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in Wolff-Parkinson-White (WPW) syndrome or short PR syndrome.
2. ***Paroxysmal Supraventricular Tachycardia.*** Rapid conversion of paroxysmal supraventricular tachycardias (PSVT) to sinus rhythm. This includes AV nodal reentrant tachycardias and reciprocating tachycardias associated with an extranodal accessory pathway such as the WPW syndrome or short PR syndrome. Unless otherwise contraindicated, appropriate vagal maneuvers should be attempted prior to administration of CARDIZEM Injectable.

The use of CARDIZEM Injectable for control of ventricular response in patients with atrial fibrillation or atrial flutter or conversion to sinus rhythm in patients with PSVT should be undertaken with caution when the patient is compromised hemodynamically or is taking other drugs that decrease any or all of the following: peripheral resistance, myocardial filling, myocardial contractility, or electrical impulse propagation in the myocardium.

For either indication and particularly when employing continuous intravenous infusion, the setting should include continuous monitoring of the ECG and frequent measurement of blood pressure. A defibrillator and emergency equipment should be readily available.

In domestic controlled trials in patients with atrial fibrillation or atrial flutter, bolus administration of CARDIZEM Injectable was effective in reducing heart rate by at least 20% in 95% of patients. CARDIZEM Injectable rarely converts atrial fibrillation or atrial flutter to normal sinus rhythm. Following administration of one or two intravenous bolus doses of CARDIZEM Injectable, response usually occurs within 3 minutes and maximal heart rate reduction generally occurs in 2 to 7 minutes. Heart rate reduction may last from 1 to 3 hours. If hypotension occurs, it is generally short-lived, but may last from 1 to 3 hours.

A 24-hour continuous infusion of CARDIZEM Injectable in the treatment of atrial fibrillation or atrial flutter maintained at least a 20% heart rate reduction during the infusion in 83% of patients. Upon discontinuation of infusion, heart rate reduction may last from 0.5 hours to more than 10 hours (median duration 7 hours). Hypotension, if it occurs, may be similarly persistent.

In the controlled clinical trials, 3.2% of patients required some form of intervention (typically, use of intravenous fluids or the Trendelenburg position) for blood pressure support following CARDIZEM Injectable.

In domestic controlled trials, bolus administration of CARDIZEM Injectable was effective in converting PSVT to normal sinus rhythm in 88% of patients within 3 minutes of the first or second bolus dose.

Symptoms associated with the arrhythmia were improved in conjunction with decreased heart rate or conversion to normal sinus rhythm following administration of CARDIZEM Injectable.

CONTRAINDICATIONS

CARDIZEM Injectable is contraindicated in:

1. Patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker.
2. Patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker.
3. Patients with severe hypotension or cardiogenic shock.
4. Patients who have demonstrated hypersensitivity to the drug.
5. Intravenous diltiazem and intravenous beta-blockers should not be administered together or in close proximity (within a few hours).
6. Patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in WPW syndrome or short PR syndrome.

   As with other agents which slow AV nodal conduction and do not prolong the refractoriness of the accessory pathway (eg, verapamil, digoxin), in rare instances patients in atrial fibrillation or atrial flutter associated with an accessory bypass tract may experience a potentially life-threatening increase in heart rate accompanied by hypotension when treated with CARDIZEM Injectable. As such, the initial use of CARDIZEM Injectable should be, if possible, in a setting where monitoring and resuscitation capabilities, including DC cardioversion/defibrillation, are present (see OVERDOSAGE). Once familiarity of the patient's response is established, use in an office setting may be acceptable.
7. Patients with ventricular tachycardia. Administration of other calcium channel blockers to patients with wide complex tachycardia (QRS ≥ 0.12 seconds) has resulted in hemodynamic deterioration and ventricular fibrillation. It is important that an accurate pretreatment diagnosis distinguish wide complex QRS tachycardia of supraventricular origin from that of ventricular origin prior to administration of CARDIZEM Injectable.

WARNINGS

1. **Cardiac Conduction.** Diltiazem prolongs AV nodal conduction and refractoriness that may rarely result in second- or third-degree AV block in sinus rhythm. Concomitant use of diltiazem with agents known to affect cardiac conduction may result in additive effects (see Drug Interactions). If high-degree AV block occurs in sinus rhythm, intravenous diltiazem should be discontinued and appropriate supportive measures instituted (see OVERDOSAGE).
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function and in patients with a compromised myocardium, such as severe CHF, acute MI, and hypertrophic cardiomyopathy, have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Administration of oral diltiazem in patients with acute myocardial infarction and pulmonary congestion documented by x-ray on admission is contraindicated. Experience with the use of CARDIZEM Injectable in patients with impaired ventricular function is limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM Injectable therapy may occasionally result in symptomatic hypotension (3.2%). The use of intravenous diltiazem for control of ventricular response in patients with supraventricular arrhythmias should be undertaken with caution when the patient is compromised hemodynamically. In addition, caution should be used in patients taking other drugs that decrease peripheral resistance, intravascular volume, myocardial contractility or conduction.
4. **Acute Hepatic Injury.** In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted following oral diltiazem. Therefore, the potential for acute hepatic injury exists following administration of intravenous diltiazem.
5. **Ventricular Premature Beats (VPBs).** VPBs may be present on conversion of PSVT to sinus rhythm with CARDIZEM Injectable. These VPBs are transient, are typically considered to be benign, and appear to have no clinical significance. Similar ventricular complexes have been noted during cardioversion, other pharmacologic therapy, and during spontaneous conversion of PSVT to sinus rhythm.

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. The drug should be used with caution in patients with impaired renal or hepatic function (see WARNINGS). High intravenous dosages (4.5 mg/kg tid) administered to dogs resulted in significant bradycardia and alterations in AV conduction. In subacute and chronic dog and rat studies designed to produce toxicity, high oral doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver, which were reversible when the drug was discontinued. In dogs, oral doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Dermatologic events progressing to erythema multiforme and/or exfoliative dermatitis have been infrequently reported following oral diltiazem. Therefore, the potential for these dermatologic reactions exists following exposure to intravenous diltiazem. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interactions. Due to potential for additive effects, caution is warranted in patients receiving CARDIZEM Injectable concomitantly with any agent(s) known to affect cardiac contractility and/or SA or AV node conduction (see WARNINGS).

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes extensive metabolism by the cytochrome P-450 mixed function oxidase system. Although specific pharmacokinetic drug-drug interaction studies have not been conducted with single intravenous injection or constant rate intravenous infusion, coadministration of CARDIZEM Injectable with other agents which primarily undergo the same route of biotransformation may result in competitive inhibition of metabolism.

Digitalis: Intravenous diltiazem has been administered to patients receiving either intravenous or oral digitalis therapy. The combination of the two drugs was well tolerated without serious adverse effects. However, since both drugs affect AV nodal conduction, patients should be monitored for excessive slowing of the heart rate and/or AV block.

Beta-blockers: Intravenous diltiazem has been administered to patients on chronic oral beta-blocker therapy. The combination of the two drugs was generally well tolerated without serious adverse effects. If intravenous diltiazem is administered to patients receiving chronic oral beta-blocker therapy, the possibility for bradycardia, AV block, and/or depression of contractility should be considered (see CONTRAINDICATIONS). ***Oral*** administration of diltiazem with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. In vitro, propranolol appears to be displaced from its binding sites by diltiazem.

Anesthetics: The depression of cardiac contractility, conductivity, and automaticity as well as the vascular dilation associated with anesthetics may be potentiated by calcium channel blockers. When used concomitantly, anesthetics and calcium blockers should be titrated carefully.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats at oral dosage levels of up to 100 mg/kg/day, and a 21-month study in mice at oral dosage levels of up to 30 mg/kg/day showed no evidence of carcinogenicity. There was also no mutagenic response in vitro or in vivo in mammalian cell assays or in vitro in bacteria. No evidence of impaired fertility was observed in a study performed in male and female rats at oral dosages of up to 100 mg/kg/day.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of oral doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended oral antianginal therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human oral antianginal dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Diltiazem is excreted in human milk. One report with oral diltiazem suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

The following adverse reaction rates are based on the use of CARDIZEM Injectable in over 400 domestic clinical trial patients with atrial fibrillation/flutter or PSVT under double-blind or open-label conditions. Worldwide experience in over 1,300 patients was similar.

Adverse events reported in controlled and uncontrolled clinical trials were generally mild and transient. Hypotension was the most commonly reported adverse event during clinical trials. Asymptomatic hypotension occurred in 4.3% of patients. Symptomatic hypotension occurred in 3.2% of patients. When treatment for hypotension was required, it generally consisted of administration of saline or placing the patient in the Trendelenburg position. Other events reported in at least 1% of the diltiazem-treated patients were injection site reactions (eg, itching, burning)—3.9%, vasodilation (flushing)—1.7%, and arrhythmia (junctional rhythm or isorhythmic dissociation)—1.0%.

In addition, the following events were reported infrequently (less than 1%):

Cardiovascular:	Atrial flutter, AV block first degree, AV block second degree, bradycardia, chest pain, congestive heart failure, sinus pause, sinus node dysfunction, syncope, ventricular arrhythmia, ventricular fibrillation, ventricular tachycardia.
Dermatologic:	Pruritus, sweating.
Gastrointestinal:	Constipation, elevated SGOT or alkaline phosphatase, nausea, vomiting.
Nervous System:	Dizziness, paresthesia.
Other:	Amblyopia, asthenia, dry mouth, dyspnea, edema, headache, hyperuricemia.

Although not observed in clinical trials with CARDIZEM Injectable, other reactions associated with oral diltiazem may occur.

---

We estimated the potency of vecuronium and measured the onset and duration of its action during total intravenous anesthesia with propofol to examine the possibility of any interaction between these two drugs. Propofol infusion was administered according to a three-step dosage scheme, and neuromuscular block was monitored by measuring the force of contraction of the adductor pollicis muscle after single-twitch stimulation of the ulnar nerve at 0.1 Hz. A control group of patients were similarly studied during anesthesia with thiopental, nitrous oxide, oxygen, and fentanyl. The ED_{50} and ED_{95} (dose required to produce a 50% and 95% depression of twitch tension, respectively) of vecuronium in patients given total intravenous anesthesia (n = 24) were 24 (22–27, 95% confidence limits) and 41 (37–48, 95% confidence limits) μg/kg, respectively, and in the control group (n = 24), 20 (17–24) and 39 (34–37) μg/kg, respectively. The onset of action of an 80-μg/kg dose (2 × ED_{95}) of vecuronium was 3.6 ± 1.2 and 4.1 ± 1.7 min (mean ± SD), in the propofol (n = 10) and control (n = 10) groups, respectively. The respective times to recovery of the twitch height to 25% of control and the recovery indices (25%–75% recovery of twitch height) in the propofol versus control groups were 28.3 ± 6.6 and 28.0 ± 1.7 min and 13.3 ± 6.8 and 15.4 ± 11.9 min, respectively. There were no significant differences in any of the measured variables between the propofol and control groups, indicating the lack of any interaction between propofol and vecuronium.

(Anesth Analg 1992;75:536–8)

Propofol was originally formulated in Cremophor but now is formulated as an emulsion in soybean oil and egg phosphatide. The original formulation of propofol in Cremophor may potentiate a vecuronium neuromuscular blockade in both experimental and clinical settings (1,2). Lack of significant interaction has been reported between the emulsion formulation of propofol and vecuronium (3,4). However, a cumulative instead of a single dose-response method for estimating the potency of vecuronium was used in one study (3), whereas only a single induction dose of propofol and a single relatively small dose of vecuronium were used in the other (4). Our study was designed to assess any interaction between the currently used emulsion formulation of propofol and vecuronium in humans by first estimating the potency of vecuronium using a single-dose method and then measuring the onset and duration of its action during total intravenous anesthesia with propofol.

Methods

Sixty-eight adult patients, aged 18–65 yr, undergoing body surface operations were included in the study after they gave their informed consent and after the approval of the Research Ethical Committee. All patients conformed to ASA physical status class I or II, and those with a weight >120% of ideal or on medication known to interact with neuromuscular blocking agents were excluded. Premedication consisted of oral diazepam (10 mg) administered 90 min preoperatively. All patients were monitored in the usual manner. Ventilation was adjusted to end-tidal carbon dioxide concentration of 4.5%–5.5%.

Patients were randomly allocated to be anesthetized with either a continuous propofol infusion (propofol group) and ventilation with air and oxygen or thiopental with nitrous oxide and oxygen (control group). Both groups received fentanyl (2–3 μg/kg) at induction, followed by further increments if required. In the propofol group, anesthesia was induced with a dose of 2.5 mg/kg and maintained with an infusion of propofol at a starting rate of

---

The results of this study were presented at the Annual Meeting of the American Society of Anesthesiologists, October 1990, Las Vegas, Nevada, and an abstract was published in Anesthesiology 1990;73:A899.

Accepted for publication June 1, 1992.

10 mg·kg^{-1}·h^{-1}, which was reduced at intervals of 10 min each to 8 and 6 mg·kg^{-1}·h^{-1} and then maintained at that rate, as previously reported by Roberts et al. (5). In the control group, anesthesia was induced with thiopental (4–5 mg/kg) and maintained with 70% nitrous oxide in oxygen and fentanyl as required.

The study was conducted in two phases. In phase I, 48 patients, in two groups of 24 each, were studied for estimation of potency of vecuronium during the two anesthetic techniques by constructing dose-response curves. After induction of anesthesia, the ulnar nerve was stimulated at the wrist with supramaximal stimuli at a frequency of 0.1 Hz and the resultant force of contraction of the adductor pollicis muscle was recorded with a force transducer and a neuromuscular function analyzer (Myograph 2000, Biometer Ltd.). After a 10-min stabilization period, eight patients within each anesthetic technique were randomly allocated to receive a bolus dose of 20, 30, or 40 μg/kg of vecuronium, and maximal block was allowed to supervene, regardless of the time taken to achieve it. An arc-sine transformation of the data relating to twitch height was carried out, as used previously to allow analysis of the response between 0% and 100% block (6). Dose-response curves were constructed to allow linear regression analysis to be performed and ED_{50} and ED_{95} (dose required to produce a 50% and 95% depression of twitch tension, respectively) determined.

In the second phase of the study, 80 μg/kg of vecuronium was administered as a single bolus dose to 10 patients, each anesthetized with the two techniques after baseline neuromuscular monitoring was established along the same lines as in phase I. The times to onset of maximal block and to recovery of the twitch height to 25% and 75% of control (for estimating the recovery index) were determined. Analysis of variance, analysis of covariance, and *t*-tests were used to assess the statistical significance of the results, which was accepted at the 5% level.

Results

The groups were comparable as to age and weight in both phases of the study. The dose-response curves as shown in Figure 1 are close to each other. The lines did not differ significantly in their slopes. The derived values of ED_{50} and ED_{95} are given in Table 1. The ED_{50} values of 24 and 20 μg/kg and the ED_{95} values of 41 and 39 μg/kg, in the propofol and control groups respectively were not significantly different.

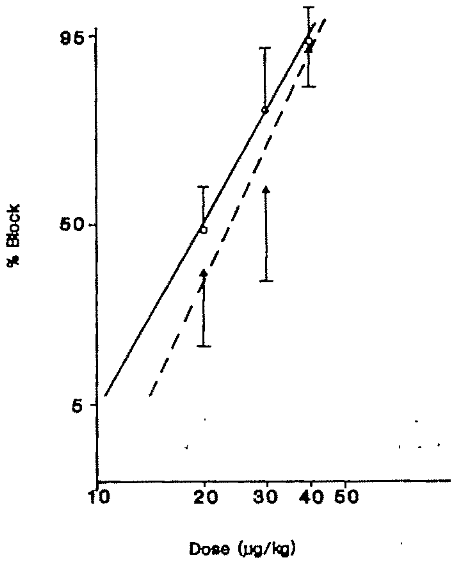

Figure 1. Dose-response curves for vecuronium during anesthesia with propofol (▲—▲) and with thiopental-nitrous oxide-oxygen-fentanyl (○—○). The *points* are the average degree of block obtained with each dose and the *bars* represent standard deviation.

Table 1. Patient Characteristics and Estimated ED_{50} and ED_{95} (95% confidence limits) in the Propofol and Control Groups

	Propofol group (n = 24)	Control group (n = 24)
Age (yr)	49 (15.9)	42 (14.3)
Weight (kg)	69 (13.9)	74 (8.4)
ED_{50} (μg/kg)	24 (22–27)	20 (17–24)
ED_{95} (μg/kg)	41 (37–48)	39 (34–37)

ED_{50}, ED_{95}, dose required to produce a 50% and 95% depression of twitch tension, respectively.
Mean (±SD).

Table 2. Patient Characteristics and Results From the Onset and Duration Phase of the Study

	Propofol group (n = 10)	Control group (n = 10)
Age (yr)	46 (15.2)	46 (15.9)
Weight (kg)	71 (10.5)	67 (11.1)
Time to maximal block (min)	3.6 (1.2)	4.1 (1.7)
Time to return of T-1 to 25% (min)	28.3 (6.6)	28 (1.7)
Recovery index (min)	13.3 (6.8)[a]	15.4 (11.9)[b]

Mean (±SD).
[a] Nine patients.
[b] Seven patients.

The time to maximal block (100% in all cases) was similar between the groups (3.6 and 4.1 min in the propofol and control groups, respectively) without any significant difference. The time to 25% recovery of twitch height (≈28 min) and the recovery indices (13–15 min) also showed no significant difference between the groups (Table 2).

Discussion

Our results showed no differences in the estimates of potency or the onset and duration of action of vecuronium when used in single doses during propofol-fentanyl anesthesia and thiopental-fentanyl-N_2O anesthesia. This is contrary to the results of an in vitro study in which the effects of vecuronium were potentiated (1), but in that study the Cremophor formulation was used. The difference may thus have been due to Cremophor, although it has been proposed that Cremophor may actually have anticholinesterase properties (1).

In the first phase of our study, we assessed the dose-response relationship for vecuronium in humans. There was no significant difference in our final estimates of the ED_{95} for vecuronium with or without propofol, and the values obtained were indeed similar to those previously reported using a similar technique of estimation (6).

In the second phase of the study, we found no difference between the groups in terms of the onset time. Onset of neuromuscular blockade is largely dependent on cardiac output and muscle blood flow to deliver the drug to its receptor site, and the potency, affinity, or diffusion characteristics of the drug are of secondary importance (7). Hence, the lack of any difference in onset time is not surprising. We might have expected a difference only if there was a marked alteration in cardiac output between the two anesthetic techniques used. The subsequent recovery of neuromuscular function occurs as the plasma concentration of vecuronium declines with redistribution and metabolism. Because there was no significant difference between the groups in the time to recovery to 25% of control twitch height, or in the time for spontaneous recovery from 25% to 75% of control, we must conclude that there is no evidence for any significant interaction. We are able to confirm the findings of previous workers with respect to a lack of interaction between the emulsion formulation of propofol and vecuronium (3), although these authors used a cumulative dose-response technique. In addition, they used a relatively small dose of 43 μg/kg of vecuronium to study the onset and duration in contrast to a clinically applicable dose of 80 μg/kg used in the present study. The study of Nightingale et al. (4) is not directly comparable to ours, even though the results were similar. Whereas we used propofol for both induction and maintenance of anesthesia, they assessed the effects of only an induction dose of propofol. Moreover, they examined the effects of only a small single dose of vecuronium that produced approximately 50% block; in addition, they used electromyography for measurement of neuromuscular block.

The original animal studies using the Cremophor preparation led to the suggestion that any interaction was a direct intracellular effect of propofol on the muscle (1) rather than due to the effect of Cremophor, because Cremophor was suggested by these authors to have an anticholinesterase effect. They further speculated that a non-Cremophor preparation may prolong the effect of muscle relaxants even more markedly. However, these explanations are not relevant in the context of the present study, where the emulsion formulation showed no potentiation of the effects of vecuronium. Moreover, the Cremophor preparation is no longer in use. As no interaction has been observed between clinically useful doses of thiopental and vecuronium (8), the possibility that we have masked the action of propofol by the use of thiopental in our control groups seems unlikely.

In conclusion, the emulsion formulation of propofol does not have any significant effect on the neuromuscular blocking properties of vecuronium in humans.

A Long-Acting Neuromuscular Blocker

NUROMAX® INJECTION
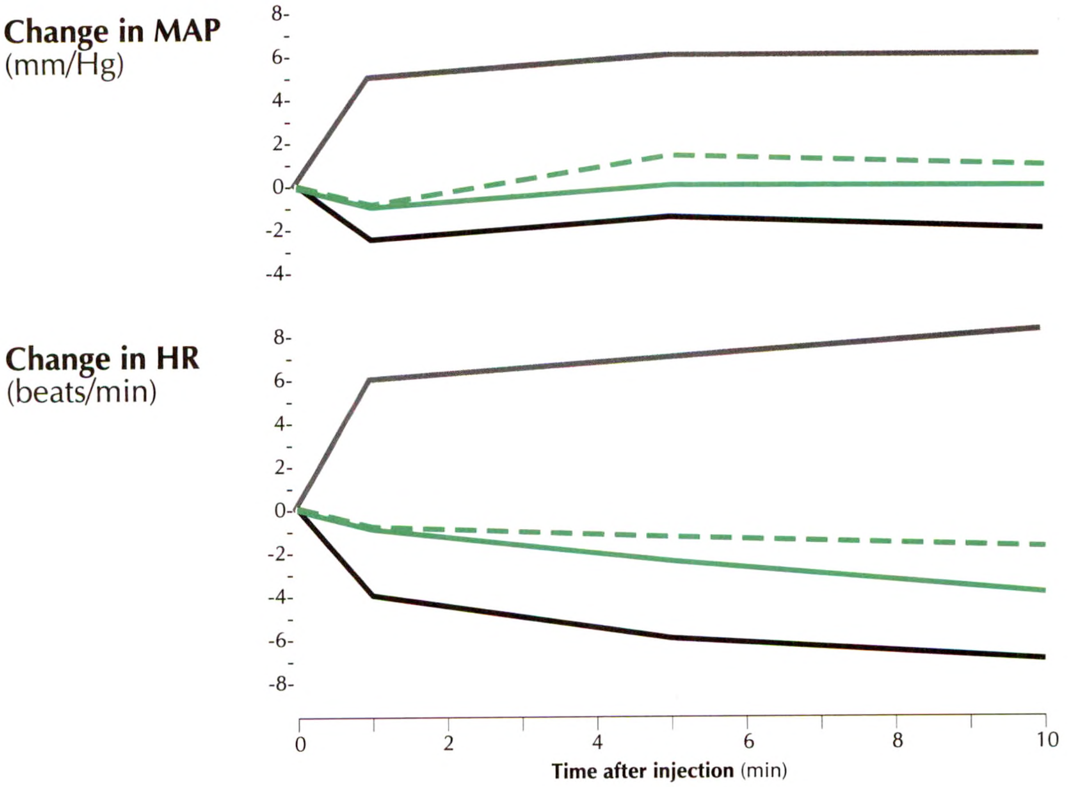
(doxacurium chloride)

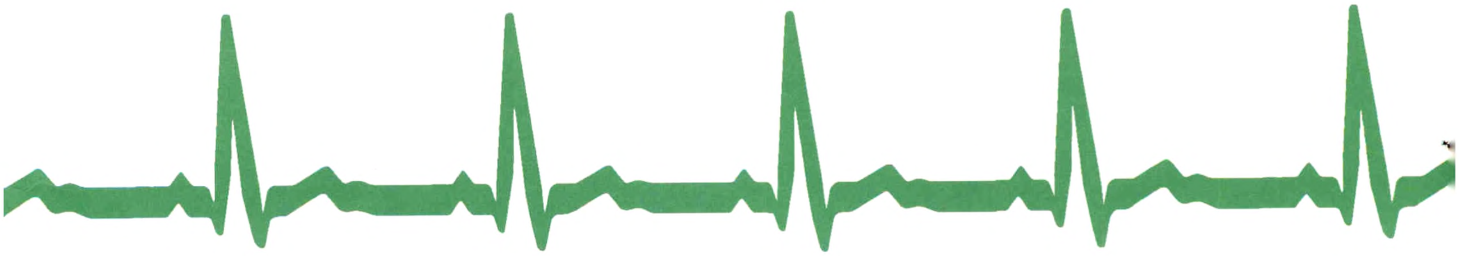
Excellent CV Stability

Cardiovascular stability comparable with vecuronium



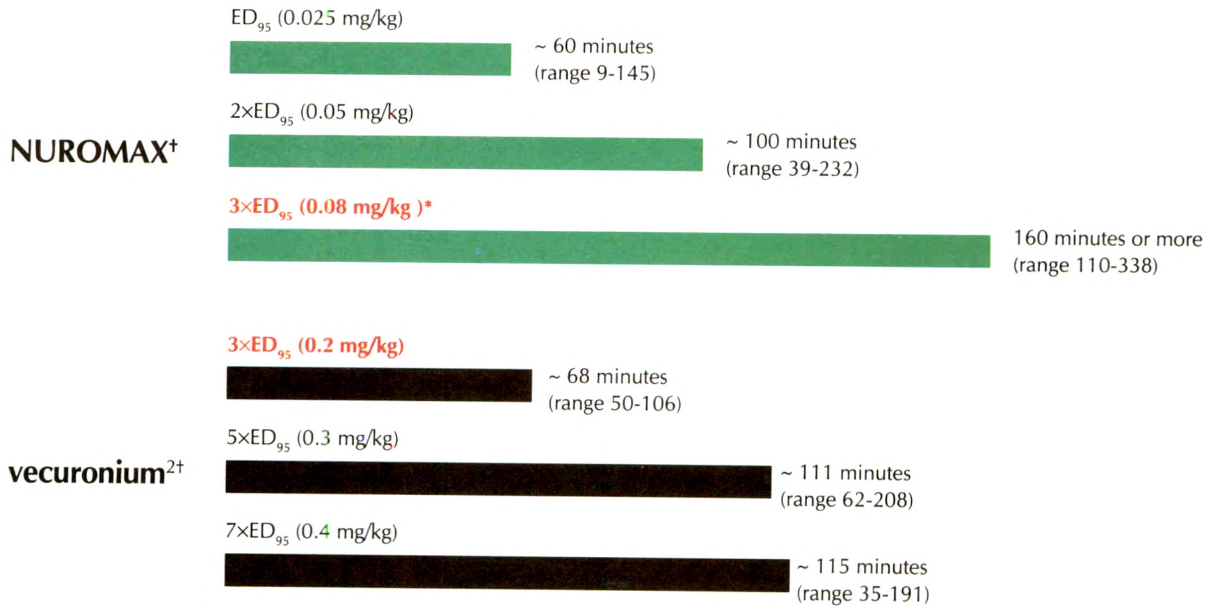
Emmott et al[1] compared the hemodynamic effects of Nuromax 0.037 and 0.075 mg/kg with the effects of pancuronium 0.09 mg/kg and vecuronium 0.075 mg/kg in 36 CABG patients (9 patients, each group).
Mean changes from baseline values of mean systemic arterial pressure (MAP) and heart rate (HR) at 1, 5 and 10 min after administration.
All routine cardiac and vasoactive medications were continued up to the morning of surgery.

- – – doxacurium 0.037 mg/kg
- ─── doxacurium 0.075 mg/kg
- ▨▨▨ pancuronium 0.09 mg/kg
- ━━━ vecuronium 0.075 mg/kg



Longer acting than "high-dose" vecuronium

Clinically effective block (time to 25% recovery)



---

*This dose should be reserved for instances in which a need for very prolonged neuromuscular block is anticipated.

NUROMAX® INJECTION

(doxacurium chloride) 1 mg/mL

Excellent for Long CV Procedures

Please see brief summary of full prescribing information.

NUROMAX® INJECTION
(DOXACURIUM CHLORIDE)

Brief Summary

This drug should be administered only by adequately trained individuals familiar with its actions, characteristics, and hazards.

Individualization of Dosages: In elderly patients or patients who have impaired renal function, the potential for a prolongation of block may be reduced by decreasing the initial Nuromax dose and by titrating the dose to achieve the desired depth of block. In obese patients (patients weighing $\geq$ 30% more than ideal body weight for height), the Nuromax dose should be determined using the patient's ideal body weight (IBW), according to the following formulae:

Men: IBW in kg = [106 + (6 x inches in height above 5 feet)]/2.2
Women: IBW in kg = [100 + (5 x inches in height above 5 feet)]/2.2

Dosage requirements for patients with severe liver disease are variable; some patients may require a higher than normal initial Nuromax dose to achieve clinically effective block. Once adequate block is established, the clinical duration of block may be prolonged in such patients relative to patients with normal liver function.

As with pancuronium, metocurine, and vecuronium, resistance to Nuromax, manifested by a reduced intensity and/or shortened duration of block, must be considered when Nuromax is selected for use in patients receiving phenytoin or carbamazepine (see **Drug Interactions** subsection of PRECAUTIONS).

As with other nondepolarizing neuromuscular blocking agents, a reduction in dosage of Nuromax must be considered in cachectic or debilitated patients, in patients with neuromuscular diseases, severe electrolyte abnormalities, or carcinomatosis, and in other patients in whom potentiation of neuromuscular block or difficulty with reversal is anticipated. Increased doses of Nuromax may be required in burn patients (see PRECAUTIONS).

INDICATIONS AND USAGE: Nuromax is a long-acting neuromuscular blocking agent, indicated as an adjunct to general anesthesia, to provide skeletal muscle relaxation during surgery. Nuromax can also be used to provide skeletal muscle relaxation for endotracheal intubation.

CONTRAINDICATIONS: Nuromax is contraindicated in patients known to have hypersensitivity to it.

WARNINGS: NUROMAX SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH THE DRUG'S ACTIONS AND THE POSSIBLE COMPLICATIONS OF ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND AN ANTAGONIST ARE WITHIN IMMEDIATE REACH. IT IS RECOMMENDED THAT CLINICIANS ADMINISTERING LONG-ACTING NEUROMUSCULAR BLOCKING AGENTS SUCH AS NUROMAX EMPLOY A PERIPHERAL NERVE STIMULATOR TO MONITOR DRUG RESPONSE, NEED FOR ADDITIONAL RELAXANTS, AND ADEQUACY OF SPONTANEOUS RECOVERY OR ANTAGONISM.

NUROMAX HAS NO KNOWN EFFECT ON CONSCIOUSNESS, PAIN THRESHOLD, OR CEREBRATION. TO AVOID DISTRESS TO THE PATIENT, NEUROMUSCULAR BLOCK SHOULD NOT BE INDUCED BEFORE UNCONSCIOUSNESS.

Nuromax Injection is acidic (pH 3.9 to 5.0) and may not be compatible with alkaline solutions having a pH greater than 8.5 (*e.g.*, barbiturate solutions).

Nuromax Injection contains benzyl alcohol. In newborn infants, benzyl alcohol has been associated with an increased incidence of neurological and other complications which are sometimes fatal. See **Pediatric Use** subsection of PRECAUTIONS.

PRECAUTIONS: General: Nuromax has no clinically significant effects on heart rate; therefore, Nuromax will not counteract the bradycardia produced by many anesthetic agents or by vagal stimulation. Neuromuscular blocking agents may have a profound effect in patients with neuromuscular diseases (*e.g.*, myasthenia gravis and the myasthenic syndrome). In these and other conditions in which prolonged neuromuscular block is a possibility (*e.g.*, carcinomatosis), the use of a peripheral nerve stimulator and a small test dose of Nuromax is recommended to assess the level of neuromuscular block and to monitor dosage requirements. Shorter acting muscle relaxants than Nuromax may be more suitable for these patients.

Resistance to nondepolarizing neuromuscular blocking agents may develop in patients with burns depending upon the time elapsed since the injury and the size of the burn. Nuromax has not been studied in patients with burns. Acid-base and/or serum electrolyte abnormalities may potentiate or antagonize the action of neuromuscular blocking agents. The action of neuromuscular blocking agents may be enhanced by magnesium salts administered for the management of toxemia of pregnancy. Nuromax has not been studied in patients with asthma. No data are available to support the use of Nuromax by intramuscular injection. **Renal and Hepatic Disease:** Nuromax has been studied in patients with end-stage kidney (n=8) or liver (n=7) disease undergoing transplantation procedures (see CLINICAL PHARMACOLOGY). The possibility of prolonged neuromuscular block in patients undergoing renal transplantation and the possibility of a variable onset and duration of neuromuscular block in patients undergoing liver transplantation must be considered when Nuromax is used in such patients. **Obesity:** Administration of Nuromax on the basis of actual body weight is associated with a prolonged duration of action in obese patients (patients weighing $\geq$ 30% more than ideal body weight for height) (see CLINICAL PHARMACOLOGY). Therefore, the dose of Nuromax should be based upon ideal body weight in obese patients (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY). **Malignant Hyperthermia (MH):** In a study of MH-susceptible pigs, Nuromax did not trigger MH. Nuromax has not been studied in MH-susceptible patients. Since MH can develop in the absence of established triggering agents, the clinician should be prepared to recognize and treat MH in any patient scheduled for general anesthesia. **Long-Term Use in the Intensive Care Unit (ICU):** No data are available on the long-term use of Nuromax in patients undergoing mechanical ventilation in the ICU. **Drug Interactions:** Prior administration of succinylcholine has no clinically important effect on the neuromuscular blocking action of Nuromax. The use of Nuromax before succinylcholine to attenuate some of the side effects of succinylcholine has not been studied. There are no clinical data on concomitant use of Nuromax and other nondepolarizing neuromuscular blocking agents. Isoflurane, enflurane and halothane decrease the ED_{50} of Nuromax by 30% to 45%. These agents may also prolong the clinically effective duration of action by up to 25%. Other drugs which may enhance the neuromuscular blocking action of nondepolarizing agents such as Nuromax include certain antibiotics (*e.g.*, aminoglycosides, tetracyclines, bacitracin, polymyxins, lincomycin, clindamycin, colistin, and sodium colistimethate), magnesium salts, lithium, local anesthetics, procainamide, and quinidine. As with some other nondepolarizing neuromuscular blocking agents, the time of onset of neuromuscular block induced by Nuromax is lengthened and the duration of block is shortened in patients receiving phenytoin or carbamazepine. **Carcinogenesis, Mutagenesis, Impairment of Fertility:** Carcinogenesis and fertility studies have not been performed. Nuromax was evaluated in a battery of four short-term mutagenicity tests. It was non-mutagenic in the Ames Salmonella assay, in the mouse lymphoma assay, and in the human lymphocyte assay. In the *in vivo* rat bone marrow cytogenetic assay, statistically significant increases in the incidence of structural abnormalities, relative to vehicle controls, were observed in male rats dosed with 0.1 mg/kg (0.625 mg/m^2) Nuromax and sacrificed at 6 hours, but not at 24 or 48 hours, and in female rats dosed with 0.2 mg/kg (1.25 mg/m^2) Nuromax and sacrificed at 24 hours, but not at 6 or 48 hours. There was no increase in structural abnormalities in either male or female rats given 0.3 mg/kg (1.875 mg/m^2) Nuromax and sacrificed at 6, 24, or 48 hours. Thus, the incidence of abnormalities in the *in vivo* rat bone marrow cytogenetic assay was not dose-dependent and, therefore, the likelihood that the observed abnormalities were treatment-related or clinically significant is low. **Pregnancy:** Teratogenic Effects: Pregnancy Category C. Teratology testing in nonventilated, pregnant rats and mice treated subcutaneously with maximum subparalyzing doses of Nuromax revealed no maternal or fetal toxicity or teratogenic effects. There are no adequate and well-controlled studies of Nuromax in pregnant women. Because animal studies are not always predictive of human response and the doses used were subparalyzing, Nuromax should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Labor and Delivery:** The use of Nuromax during labor, vaginal delivery, or cesarean section has not been studied. It is not known whether Nuromax administered to the mother has immediate or delayed effects on the fetus. The duration of action of Nuromax exceeds the usual duration of operative obstetrics (cesarean section). Therefore, Nuromax is not recommended for use in patients undergoing C-section. **Nursing Mothers:** It is not known whether Nuromax is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised following Nuromax administration to a nursing woman. **Pediatric Use:** Nuromax has not been studied in children below the age of 2 years. See CLINICAL PHARMACOLOGY and DOSAGE AND ADMINISTRATION for clinical experience and recommendations for use in children 2 to 12 years of age. **Geriatric Use:** Nuromax has been used in elderly patients, including patients with significant cardiovascular disease. In elderly patients the onset of maximum block is slower and the duration of neuromuscular block produced by Nuromax is more variable and, in some cases, longer than in young adult patients (see **Pharmacodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY).

ADVERSE REACTIONS: The most frequent adverse effect of nondepolarizing blocking agents as a class consists of an extension of the pharmacological action beyond the time needed for surgery and anesthesia. This effect may vary from skeletal muscle weakness to profound and prolonged skeletal muscle paralysis resulting in respiratory insufficiency and apnea which require manual or mechanical ventilation until recovery is judged to be clinically adequate (see OVERDOSAGE). Inadequate reversal of neuromuscular block from Nuromax is possible, as with all nondepolarizing agents. Prolonged neuromuscular block and inadequate reversal may lead to postoperative complications. **Observed in Clinical Trials:** Adverse experiences were uncommon among the 1034 surgical patients and volunteers who received Nuromax and other drugs in U.S. clinical studies in the course of a wide variety of procedures conducted during balanced or inhalational anesthesia. The following adverse experiences were reported in patients administered Nuromax (all events judged by investigators during the clinical trials to have a possible causal relationship):

Incidence Greater than 1% - None

Incidence Less than 1% -

Cardiovascular[*]:	hypotension,[†] flushing,[†] ventricular fibrillation, myocardial infarction
Respiratory:	bronchospasm, wheezing
Dermatological:	urticaria, injection site reaction
Special Senses:	diplopia
Nonspecific:	difficult neuromuscular block reversal, prolonged drug effect, fever

[*] Reports of ventricular fibrillation (n=1) and myocardial infarction (n=1) were limited to ASA Class 3-4 patients undergoing cardiac surgery (n=142).

[†] 0.3% incidence. All other reactions unmarked were $\leq$ 0.1%.

OVERDOSAGE: Overdosage with neuromuscular blocking agents may result in neuromuscular block beyond the time needed for surgery and anesthesia. The primary treatment is maintenance of a patent airway and controlled ventilation until recovery of normal neuromuscular function is assured. Once evidence of recovery from neuromuscular block is observed, further recovery may be facilitated by administration of an anticholinesterase agent (*e.g.*, neostigmine, edrophonium) in conjunction with an appropriate anticholinergic agent (see **Antagonism of Neuromuscular Block**).

Antagonism of Neuromuscular Block: ANTAGONISTS (SUCH AS NEOSTIGMINE) SHOULD NOT BE ADMINISTERED PRIOR TO THE DEMONSTRATION OF SOME SPONTANEOUS RECOVERY FROM NEUROMUSCULAR BLOCK. THE USE OF A NERVE STIMULATOR TO DOCUMENT RECOVERY AND ANTAGONISM OF NEUROMUSCULAR BLOCK IS RECOMMENDED. T_4/T_1 SHOULD BE > ZERO BEFORE ANTAGONISM IS ATTEMPTED.

In an analysis of patients in whom antagonism of neuromuscular block was evaluated following administration of single doses of neostigmine averaging 0.06 mg/kg (range: 0.05 to 0.075) administered at approximately 25% T_1 spontaneous recovery during balanced anesthesia, 71% of patients exhibited $T_4/T_1 \geq 0.7$ before monitoring was discontinued. For these patients, the mean time to $T_4/T_1 \geq 0.7$ was 19 minutes (range: 7 to 55). As with other long-acting nondepolarizing neuromuscular blocking agents, the time for recovery of neuromuscular function following administration of neostigmine is dependent upon the level of residual neuromuscular block at the time of attempted reversal; longer recovery times than those cited above may be anticipated when neostigmine is administered at more profound levels of block (*i.e.*, at < 25% T_1 recovery).

Patients should be evaluated for adequate clinical evidence of antagonism, *e.g.*, 5-second head lift, and grip strength. Ventilation must be supported until no longer required. As with other neuromuscular blocking agents, physicians should be alert to the possibility that the action of the drugs used to antagonize neuromuscular block may wear off before the effects of Nuromax on the neuromuscular junction have declined sufficiently.

Antagonism may be delayed in the presence of debilitation, carcinomatosis, and the concomitant use of certain broad spectrum antibiotics, or anesthetic agents and other drugs which enhance neuromuscular block or separately cause respiratory depression (see **Drug Interactions** subsection of PRECAUTIONS). Under such circumstances the management is the same as that of prolonged neuromuscular block.

In clinical trials, a dose of 1 mg/kg edrophonium was not as effective as a dose of 0.06 mg/kg neostigmine in antagonizing moderate to deep levels of neuromuscular block (i.e., < 60% T_1 recovery). Therefore, the use of 1 mg/kg edrophonium is not recommended for reversal from moderate to deep levels of block. The use of pyridostigmine has not been studied.

Adults: *Initial Doses:* When administered as a component of a thiopental/narcotic induction-intubation paradigm as well as for production of long-duration neuromuscular block during surgery, 0.05 mg/kg (2 x ED_{95}) Nuromax produces good-to-excellent conditions for tracheal intubation in 5 minutes in approximately 90% of patients. Lower doses of Nuromax may result in a longer time for development of satisfactory intubation conditions. Clinically effective neuromuscular block may be expected to last approximately 100 minutes on average (range: 39 to 232) following 0.05 mg/kg Nuromax administered to patients receiving balanced anesthesia.

An initial Nuromax dose of 0.08 mg/kg (3 x ED_{95}) should be reserved for instances in which a need for very prolonged neuromuscular block is anticipated. In approximately 90% of patients, good-to-excellent intubation conditions may be expected in 4 minutes after this dose; however, clinically effective block may be expected to persist for as long as 160 minutes or more (range: 110 to 338) (see CLINICAL PHARMACOLOGY).

STORAGE: Store Nuromax Injection at room temperature of 15° to 25°C (59° to 77°F). DO NOT FREEZE.

THE ADVANTAGE OF CO-INDUCTION

Anesthetic Synergy

VERSED first, followed by a second anesthetic

When given first, a small dose of VERSED® (midazolam HCl/Roche) may lower the induction ED_{50} of barbiturates or narcotics up to 75%.[1-4] This synergistic effect appears o result from a mutual enhancement of binding-site affinity.[1-3] Clinically, co-induction may decrease toxicity and speed recovery.[2] VERSED can also abolish the excitatory effects and emergence phenomena associated with some induction agents,[5] and its potent amnestic effect may avoid breakthrough awareness at times when short-acting induction agents may be wearing off.

- **Allows lower doses of induction agents[1-5]**
- **A smooth induction[5]**
- **Less risk of breakthrough awareness[5]**
- **A smooth emergence[5]**

Dosing considerations

When VERSED is used before other intravenous agents for induction of anesthesia, the initial dose of each agent may be significantly reduced, at times to as low as 25% of the usual initial dose of the individual agents.

As a standard precaution, prior to I.V. administration of VERSED in any dose, oxygen and resuscitative equipment should be immediately available. VERSED should be used as an induction agent only by persons trained in anesthesiology and who are familiar with all dosing and administration guidelines. Reduce dosage in elderly or debilitated patients, in patients receiving narcotic premedication and in those with limited pulmonary reserve.

It is recommended that patients do not drive or operate hazardous machinery after receiving VERSED until the effects of the drug (*e.g.,* drowsiness) are gone or until the day after anesthesia, whichever is longer. The decision must be individualized.

Please see summary of product information on following page.

INJECTABLE

VERSED®

midazolam HCl/Roche Ⓒⅳ

FIRST

Injectable VERSED is available in 1 mg/mL and 5 mg/mL strengths.

VERSED®
midazolam HCl/Roche ℞
INJECTION

Before prescribing, please consult complete product information, a summary of which follows:

> Intravenous VERSED has been associated with respiratory depression and respiratory arrest, especially when used for conscious sedation. In some cases, where this was not recognized promptly and treated effectively, death or hypoxic encephalopathy has resulted. Intravenous VERSED should be used only in hospital or ambulatory care settings, including physicians' offices, that provide for continuous monitoring of respiratory and cardiac function. Immediate availability of resuscitative drugs and equipment and personnel trained in their use should be assured. (See WARNINGS.)
> The initial intravenous dose for conscious sedation may be as little as 1 mg, but should not exceed 2.5 mg in a normal healthy adult. Lower doses are necessary for older (over 60 years) or debilitated patients and in patients receiving concomitant narcotics or other CNS depressants. The initial dose and all subsequent doses should never be given as a bolus; administer over at least 2 minutes and allow an additional 2 or more minutes to fully evaluate the sedative effect. The use of the 1 mg/mL formulation or dilution of the 1 mg/mL or 5 mg/mL formulation is recommended to facilitate slower injection. Consult complete product information under DOSAGE AND ADMINISTRATION for complete dosing information.

CONTRAINDICATIONS: Patients with known hypersensitivity to the drug. Benzodiazepines are contraindicated in patients with acute narrow angle glaucoma; may be used in open angle glaucoma only if patients are receiving appropriate therapy.

Not intended for intrathecal or epidural administration due to the presence of the preservative benzyl alcohol.

WARNINGS: Never use without individualization of dosage. Prior to IV use in any dose, ensure immediate availability of oxygen, resuscitative equipment and skilled personnel for maintenance of a patent airway and support of ventilation. Continuously monitor for early signs of underventilation or apnea, which can lead to hypoxia/cardiac arrest unless effective countermeasures are taken immediately. Vital signs should continue to be monitored during the recovery period.

Because IV VERSED depresses respiration, and opioid agonists and other sedatives can add to this depression, it should be administered as an induction agent only by a person trained in general anesthesia and should be used for conscious sedation only in the presence of personnel skilled in early detection of underventilation, maintaining a patent airway and supporting ventilation. **For conscious sedation, do not administer IV by rapid or single bolus.** Serious cardiorespiratory adverse events have occurred. These have included respiratory depression, apnea, respiratory arrest and/or cardiac arrest, sometimes resulting in death. There have been rare reports of hypotensive episodes requiring treatment during or after diagnostic or surgical manipulations in patients who have received VERSED. Hypotension occurred more frequently in the conscious sedation studies in patients premedicated with narcotic.

Reactions such as agitation, involuntary movements, hyperactivity and combativeness have been reported. These may be due to inadequate or excessive dosing or improper administration; however, the possibility of cerebral hypoxia or true paradoxical reactions should be considered. Should these reactions occur, response to each dose of VERSED and all other drugs should be evaluated before proceeding.

Concomitant use of barbiturates, alcohol or other CNS depressants may increase the risk of underventilation or apnea and may contribute to profound and/or prolonged drug effect. Narcotic premedication also depresses the ventilatory response to carbon dioxide stimulation.

Higher risk surgical, elderly or debilitated patients require lower dosages for induction of anesthesia, premedicated or not. Patients with chronic obstructive pulmonary disease are unusually sensitive to the respiratory depressant effect of VERSED. Patients with chronic renal failure and patients with congestive heart failure eliminate midazolam more slowly. Because elderly patients frequently have inefficient function of one or more organ systems, and because dosage requirements have been shown to decrease with age, reduce initial dosage and consider possibility of a profound and/or prolonged effect.

Do not administer in shock, coma, acute alcohol intoxication with depression of vital signs. Particular care should be exercised in the use of IV VERSED in patients with uncompensated acute illnesses, such as severe fluid or electrolyte disturbances.

Guard against unintended intra-arterial injection; hazards in humans unknown. Avoid extravasation.

VERSED should only be administered IM or IV. Safety and efficacy of other routes of administration are not established.

Gross tests of recovery from the effects of VERSED cannot alone predict reaction time under stress. This drug is never used alone during anesthesia, and the contribution of other perioperative drugs and events can vary. The decision as to when patients may engage in activities requiring mental alertness must be individualized; it is recommended that no patient should operate hazardous machinery or a motor vehicle until the effects of the drug, such as drowsiness, have subsided or until the day after anesthesia, whichever is longer.

Usage in Pregnancy: An increased risk of congenital malformations associated with the use of benzodiazepines (diazepam and chlordiazepoxide) has been suggested in several studies. If VERSED is used during pregnancy, apprise the patient of the potential hazard to the fetus.

PRECAUTIONS: *General:* Decrease intravenous doses in elderly and debilitated patients. These patients will also probably take longer to recover completely after VERSED for induction of anesthesia.

VERSED does not protect against increased intracranial pressure or against the heart rate rise and/or blood pressure rise associated with endotracheal intubation under light general anesthesia.

Information for patients: Communicate the following information and instructions to the patient when appropriate: 1. Inform your physician about any alcohol consumption and medicine you are now taking, including nonprescription drugs. Alcohol has an increased effect when consumed with benzodiazepines; therefore, caution should be exercised regarding simultaneous ingestion of alcohol and benzodiazepines. 2. Inform your physician if you are pregnant or are planning to become pregnant. 3. Inform your physician if you are nursing.

Drug Interactions: The sedative effect of IV VERSED is accentuated by premedication, particularly narcotics (*e.g.*, morphine, meperidine, fentanyl) and also secobarbital and Innovar (fentanyl and droperidol). Consequently, adjust the dosage according to the type and amount of premedication.

A moderate reduction in induction dosage requirements of thiopental (about 15%) has been noted following use of IM VERSED for premedication.

IV administration of VERSED decreases the minimum alveolar concentration (MAC) of halothane required for general anesthesia. This decrease correlates with the dose of VERSED administered.

Although the possibility of minor interactive effects has not been fully studied, VERSED and pancuronium have been used together in patients without noting clinically significant changes in dosage, onset or duration. VERSED does not protect against the characteristic circulatory changes noted after administration of succinylcholine or pancuronium, or against the increased intracranial pressure noted following administration of succinylcholine. VERSED does not cause a clinically significant change in dosage, onset or duration of a single intubating dose of succinylcholine.

No significant adverse interactions with commonly used premedications or drugs used during anesthesia and surgery (including atropine, scopolamine, glycopyrrolate, diazepam, hydroxyzine, d-tubocurarine, succinylcholine and nondepolarizing muscle relaxants) or topical local anesthetics (including lidocaine, dyclonine HCl and Cetacaine) have been observed.

Clearance of midazolam and certain other benzodiazepines may be delayed with concomitant administration of cimetidine (but not ranitidine). Clinical significance of this interaction is unclear.

Drug/laboratory test interactions: Midazolam has not been shown to interfere with clinical laboratory test results.

Carcinogenesis, mutagenesis, impairment of fertility: Midazolam maleate was administered to mice and rats for two years. At the highest dose (80 mg/kg/day) female mice had a marked increase in incidence of hepatic tumors and male rats had a small but significant increase in benign thyroid follicular cell tumors. These tumors were found after chronic use, whereas human use will ordinarily be of single or several doses.

Midazolam did not have mutagenic activity in tests that were conducted.

A reproduction study in rats did not show any impairment of fertility at up to ten times the human IV dose.

Pregnancy: Teratogenic effects: Pregnancy Category D. See WARNINGS section.

Midazolam maleate injectable, at 5 and 10 times the human dose, did not show evidence of teratogenicity in rabbits and rats.

Labor and delivery: Use in obstetrics has not been evaluated. Because midazolam is transferred transplacentally and because other benzodiazepines given in the last weeks of pregnancy have resulted in neonatal CNS depression, VERSED is not recommended for obstetrical use.

Nursing mothers: Excreted in human milk. Not recommended for use in nursing mothers.

Pediatric use: Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS: See WARNINGS concerning serious cardiorespiratory events and possible paradoxical reactions. Fluctuations in vital signs following parenteral administration were the most frequently seen findings and included decreased tidal volume and/or respiratory rate decrease (23.3% of patients following IV and 10.8% of patients following IM administration) and apnea (15.4% of patients following IV administration), as well as variations in blood pressure and pulse rate.

Following IM injection: headache (1.3%); local effects at IM site: pain (3.7%), induration (0.5%), redness (0.5%), muscle stiffness (0.3%).

IM administration to elderly and/or high-risk surgical patients has been associated with rare reports of death under circumstances compatible with cardiorespiratory depression. In most of these cases, patients also received other CNS depressants capable of depressing respiration, especially narcotics.

Following IV administration: hiccoughs (3.9%), nausea (2.8%), vomiting (2.6%), coughing (1.3%), "oversedation" (1.6%), headache (1.5%), drowsiness (1.2%); local effects at the IV site: tenderness (5.6%), pain during injection (5.0%), redness (2.6%), induration (1.7%), phlebitis (0.4%). Other effects (<1%) mainly following IV administration: *Respiratory:* Laryngospasm, bronchospasm, dyspnea, hyperventilation, wheezing, shallow respirations, airway obstruction, tachypnea. *Cardiovascular:* Bigeminy, premature ventricular contractions, vasovagal episode, bradycardia, tachycardia, nodal rhythm. *Gastrointestinal:* Acid taste, excessive salivation, retching. *CNS/Neuromuscular:* Retrograde amnesia, euphoria, hallucination, confusion, argumentativeness, nervousness, anxiety, grogginess, restlessness, emergence delirium or agitation, prolonged emergence from anesthesia, dreaming during emergence, sleep disturbance, insomnia, nightmares, athetoid movements, seizure-like activity, ataxia, dizziness, dysphoria, slurred speech, dysphonia, paresthesia. *Special Sense:* Blurred vision, diplopia, nystagmus, pinpoint pupils, cyclic movements of eyelids, visual disturbance, difficulty focusing eyes, ears blocked, loss of balance, lightheadedness. *Integumentary:* Hive-like elevation at injection site, swelling or feeling of burning, warmth or coldness at injection site. *Hypersensitivity:* Allergic reactions, including anaphylactoid reactions, hives, rash, pruritus. *Miscellaneous:* Yawning, lethargy, chills, weakness, toothache, faint feeling, hematoma.

Drug Abuse and Dependence: Available data concerning the drug abuse and dependence potential of midazolam suggest that its abuse potential is at least equivalent to that of diazepam.

OVERDOSAGE: Manifestations would resemble those observed with other benzodiazepines (*e.g.*, sedation, somnolence, confusion, impaired coordination, diminished reflexes, coma, untoward effects on vital signs). No specific organ toxicity would be expected.

DOSAGE AND ADMINISTRATION: VERSED is a potent sedative agent which requires slow administration and individualization of dosage. Clinical experience has shown VERSED to be 3 to 4 times as potent per mg as diazepam. BECAUSE SERIOUS AND LIFE-THREATENING CARDIORESPIRATORY ADVERSE EVENTS HAVE BEEN REPORTED, PROVISION FOR MONITORING, DETECTION AND CORRECTION OF THESE REACTIONS MUST BE MADE FOR EVERY PATIENT TO WHOM VERSED INJECTION IS ADMINISTERED, REGARDLESS OF AGE OR HEALTH STATUS. Excess doses or rapid or single bolus intravenous administration may result in respiratory depression and/or arrest. (See WARNINGS.) Prior to use refer to the DOSAGE AND ADMINISTRATION section in the complete product information.

Nutley, New Jersey 07110-1199

ANESTHESIOLOGISTS

Harvard Medical School/Brigham and Women's Hospital, Boston, MA has a limited number of faculty positions available for Board Certified or Board Eligible Anesthesiologists.

Brigham & Women's Hospital is a 726 bed Harvard Medical School academic teaching hospital. Anesthesia sub-specialty areas include obstetrical, cardiac, orthopedic, thoracic, neurosurgical, G.U. and GYN, in addition to general surgery. We serve both out-patients and in-patients and have a large Pain Treatment Service including both acute and chronic pain.

Faculty responsibility includes teaching, supervising and providing patient care, participation in clinical and/or basic research and administrative functions within the Department.

Salary is competitive with an excellent fringe benefit package. Applicants must be able to obtain a Massachusetts Medical license.

Interested individuals should send curriculum vitae to:

Simon Gelman, M.D., Ph.D.
Chairman, Department of Anesthesia
Brigham & Women's Hospital/
Harvard Medical School
75 Francis Street
Boston, MA 02115

Harvard Medical School/Brigham & Women's Hospital are Equal Opportunity employers.

The *International Association for the Study of Pain* announces publication of:

Management of Acute Pain: A Practical Guide

Edited by:
L. Brian Ready and W. Thomas Edwards,
Chairman and Associate Chairman of the
IASP Task Force on Acute Pain

An important new book on acute pain:

- **multidisciplinary**
- **emphasis on principles of evaluation and therapy**
- **specific technical and pharmacological information**
- **case study approach**

Fax: 206-547-1703

Level I Trauma Center ANESTHESIOLOGIST

A major emergency/trauma center in metropolitan Detroit has an immediate opening for an anesthesiologist with an interest in trauma.The position is part of a physician/certified registered nurse anesthetist practice at Detroit Receiving Hospital and University Health Center, a Level I trauma center verified by the American College of Surgeons. Detroit Receiving is affiliated with the Wayne State University School of Medicine.

An excellent compensation package is available, including paid malpractice, health, dental, life insurance and other benefits. Send C.V. to: Samuel Perov, M.D. Chief of Anesthesiology, Detroit Receiving Hospital and University Health Center, 4201 St. Antoine, Detroit, Michigan, 48201.

DIRECTOR OF PAIN MANAGEMENT

The University of Pennsylvania Department of Anesthesia seeks an individual with the skills, experience and potential to lead a group of faculty, fellows and house officers in the areas of acute and chronic pain management. The program includes acute and chronic pain management services at the Hospital of the University of Pennsylvania, and chronic pain management services at the Philadelphia Veterans Affairs Medical Center (located on the same campus) and a suburban Penn outpatient facility. The Section of Pain Management is a major program that includes both clinical and research faculty, and several fellows and residents. The program is central to the mission of the Department, and we seek candidates at the Associate Professor or Professor rank who have the knowledge and skills to direct the clinical, research and educational efforts of this Section. The University of Pennsylvania is an Equal Opportunity/Affirmative Action Employer, and we encourage applications by women and minorities. Please send Curriculm Vitae and the names of three references to:

David E. Longnecker, M.D.
Robert Dunning Dripps
Professor and Chairman
Department of Anesthesia
4 Dulles Building/HUP
3400 Spruce Street
Philadelphia, PA 19104-4283

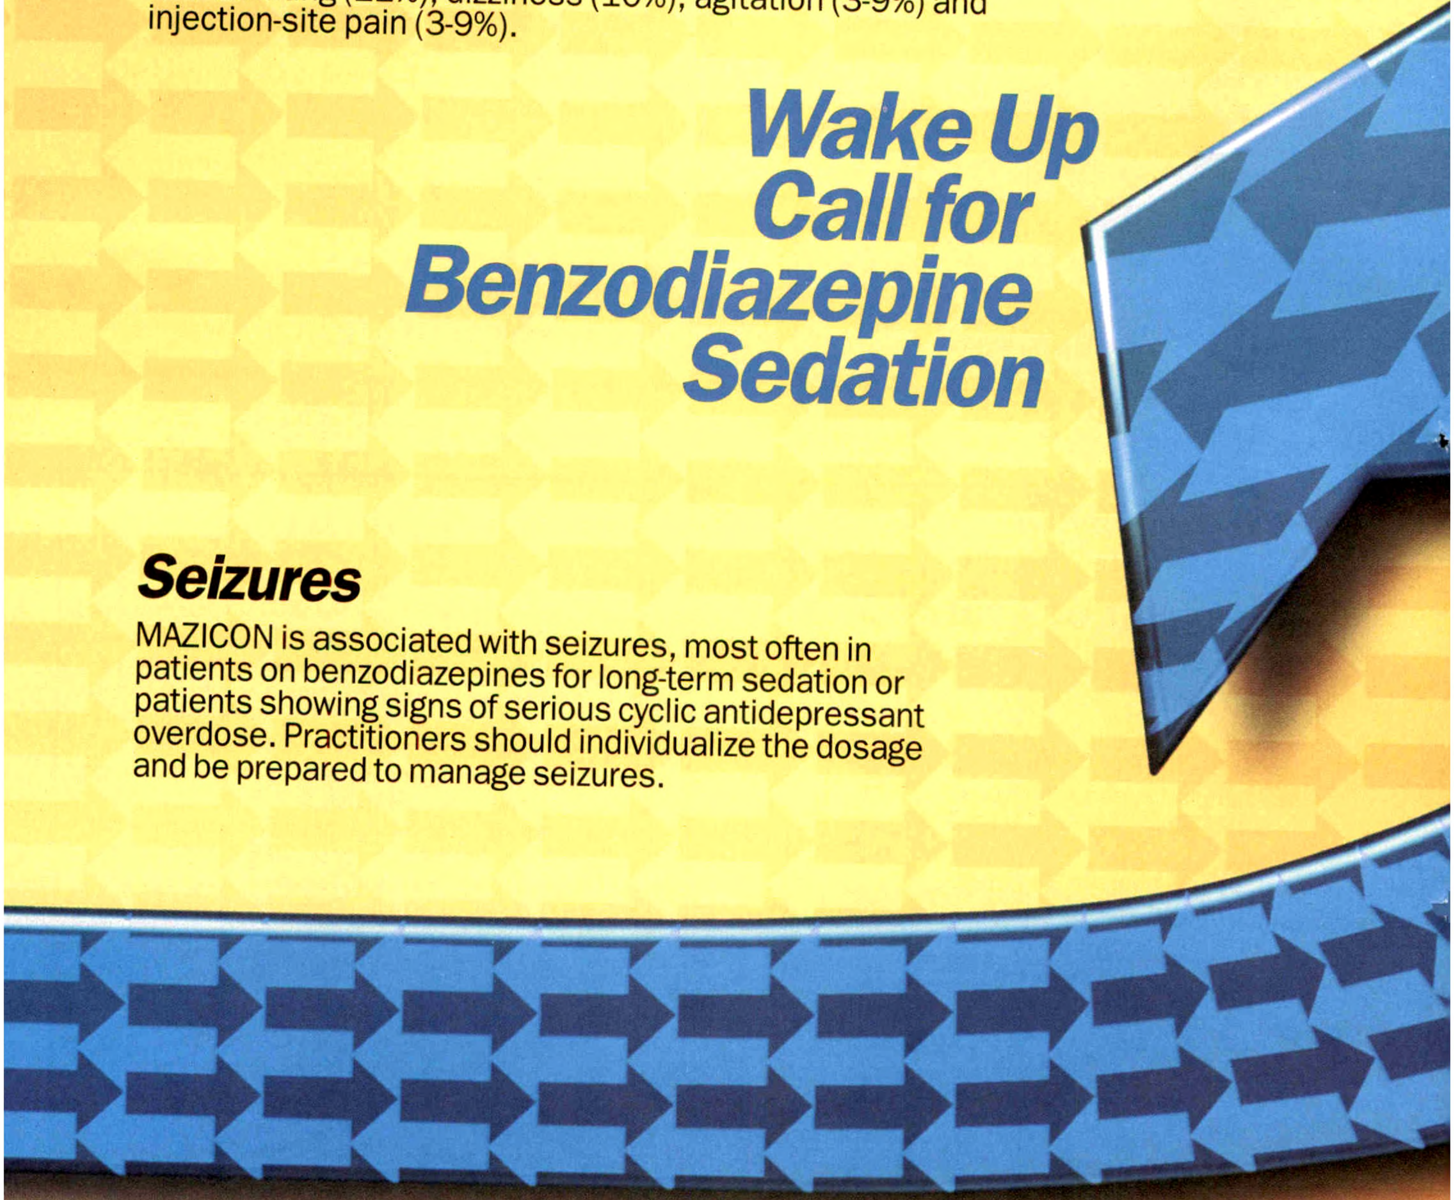
A specific reversal agent for benzodiazepine sedation

- MAZICON (flumazenil/Roche) rapidly and specifically reverses sedation produced by any benzodiazepine
- Promptly restores patients to consciousness—often within minutes of reaching an effective dose
- Reverses benzodiazepine sedative effects only—not the effects of narcotics or other CNS agents

Adverse effects

The most common side effects in clinical trials were nausea and vomiting (11%), dizziness (10%), agitation (3-9%) and injection-site pain (3-9%).

Wake Up Call for Benzodiazepine Sedation



Seizures

MAZICON is associated with seizures, most often in patients on benzodiazepines for long-term sedation or patients showing signs of serious cyclic antidepressant overdose. Practitioners should individualize the dosage and be prepared to manage seizures.

ROCHE®

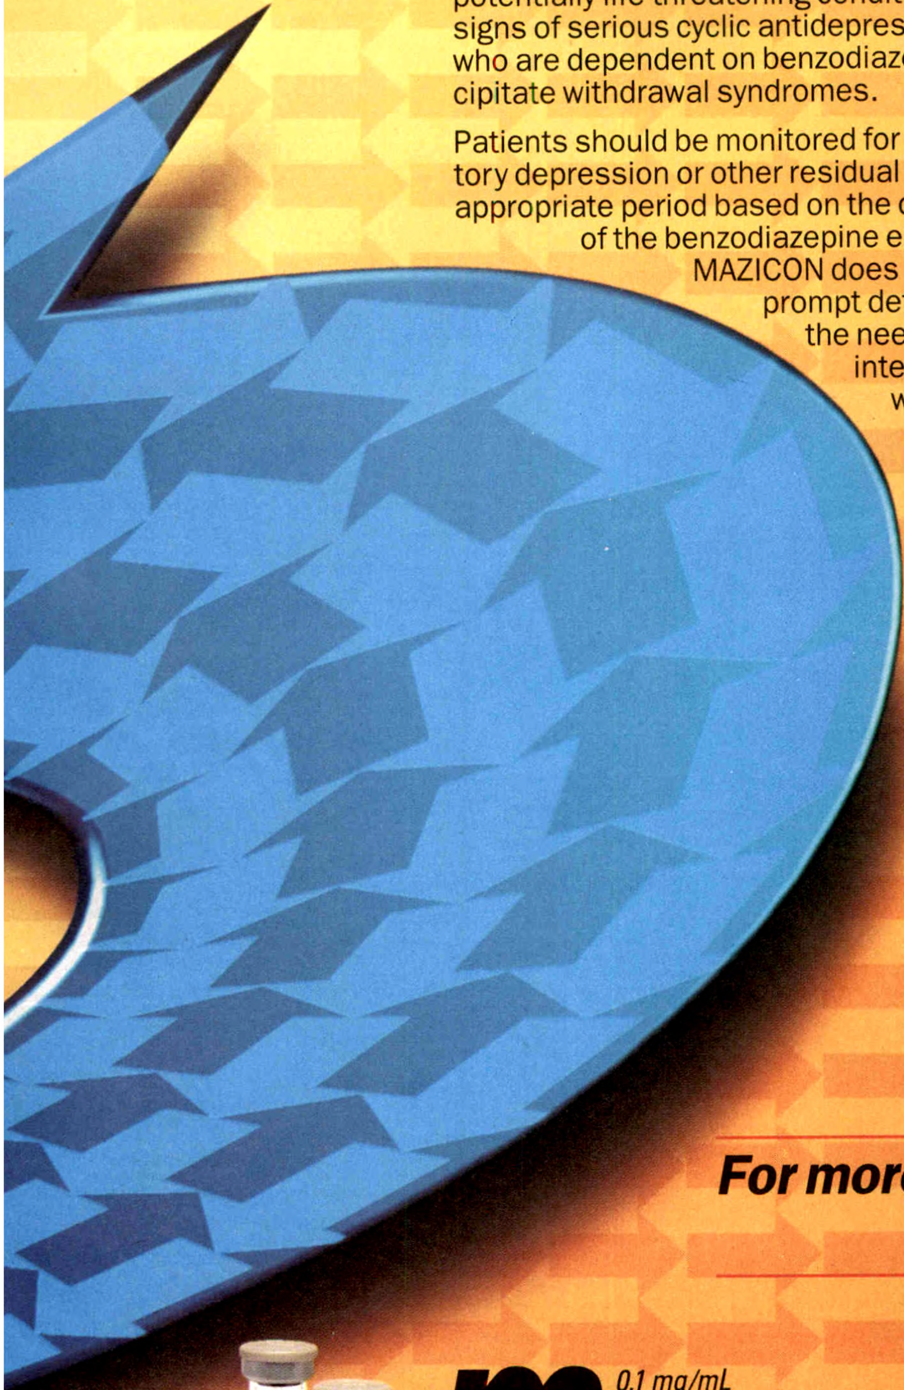
Please see complete product information on following pages.

Copyright © 1992 by Hoffmann-La Roche Inc. All rights reserved.

Important safety information

Contraindicated in hypersensitivity to benzodiazepines or MAZICON; in patients taking benzodiazepines for control of potentially life-threatening conditions; and in patients showing signs of serious cyclic antidepressant overdose. In patients who are dependent on benzodiazepines, MAZICON may precipitate withdrawal syndromes.

Patients should be monitored for possible resedation, respiratory depression or other residual benzodiazepine effects for an appropriate period based on the dose and duration of effect of the benzodiazepine employed. The availability of MAZICON does not diminish the need for prompt detection of hypoventilation and the need to be prepared to effectively intervene by establishing an airway and assisting ventilation. MAZICON has not been established as an effective treatment for benzodiazepine-induced hypoventilation.



For more information call:
1-800-756-7654

Available in
5-mL and
10-mL vials.

0.1 mg/mL
Mazicon I.V. TM
flumazenil/Roche

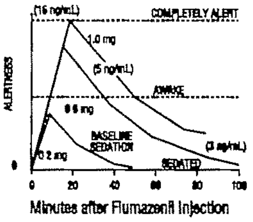
The reversal agent you've been waiting for

MAZICON™
(flumazenil/Roche)
INJECTION

DESCRIPTION: MAZICON™ (flumazenil/Roche) is a benzodiazepine receptor antagonist. Chemically, flumazenil is ethyl 8-fluoro-5,6-dihydro-5-methyl-6-oxo-4H-imidazo[1,5-a](1,4) benzodiazepine-3-carboxylate. Flumazenil has an imidazobenzodiazepine structure, a calculated molecular weight of 303.3.
Flumazenil is a white to off-white crystalline compound with an octanol:buffer partition coefficient of 14 to 1 at pH 7.4. It is insoluble in water but slightly soluble in acidic aqueous solutions. MAZICON is available as a sterile parenteral dosage form for intravenous administration. Each mL contains 0.1 mg of flumazenil compounded with 1.8 mg of methylparaben, 0.2 mg of propylparaben, 0.9% sodium chloride, 0.01% edetate disodium, and 0.01% acetic acid; the pH is adjusted to approximately 4 with hydrochloric acid and/or, if necessary, sodium hydroxide.

CLINICAL PHARMACOLOGY: Flumazenil, an imidazobenzodiazepine derivative, antagonizes the actions of benzodiazepines on the central nervous system. Flumazenil competitively inhibits the activity at the benzodiazepine recognition site on the GABA/benzodiazepine receptor complex. Flumazenil is a weak partial agonist in some animal models of activity, but has little or no agonist activity in man.
Flumazenil does not antagonize the central nervous system effects of drugs affecting GABA-ergic neurons by means other than the benzodiazepine receptor (including ethanol, barbiturates, or general anesthetics) and does not reverse the effects of opioids.
PHARMACODYNAMICS: Intravenous MAZICON has been shown to antagonize sedation, impairment of recall and psychomotor impairment produced by benzodiazepines in healthy human volunteers.
The duration and degree of reversal of benzodiazepine effects are related to the dose and plasma concentrations of flumazenil as shown in the following data from a study in normal volunteers.

Magnitude and Duration of Reversal of Sedation as a Function of Flumazenil Dose*
Flumazenil doses of 0.2, 0.6 & 1.0 mg
(blood level in ng/mL)



*Sedation produced by midazolam infusion at a rate of 0.06 - 0.20 mg/kg/hr in healthy volunteers

Generally, doses of approximately 0.1 to 0.2 mg (corresponding to peak plasma levels of 3 to 6 ng/mL) produce partial antagonism, whereas higher doses of 0.4 to 1.0 mg (peak plasma levels of 12 to 28 ng/mL) usually produce complete antagonism in patients who have received the usual sedating doses of benzodiazepines. The onset of reversal is usually evident within 1 to 2 minutes after the injection is completed. Eighty percent response will be reached within 3 minutes, with the peak effect occurring at 6 to 10 minutes. The duration and degree of reversal are related to the plasma concentration of the sedating benzodiazepine as well as the dose of MAZICON given.
In healthy volunteers, MAZICON did not alter intraocular pressure when given alone and reversed the decrease in intraocular pressure seen after administration of midazolam.
PHARMACOKINETICS: After IV administration, plasma concentrations of flumazenil follow a two compartment open pharmacokinetic model with an initial distribution half-life of 7 to 15 minutes and a terminal half-life of 41 to 79 minutes. Peak concentrations of flumazenil are proportional to dose, with an apparent initial volume of distribution of 0.5 L/kg. After redistribution the apparent volume of distribution (V_{ss}) ranges from 0.77 to 1.60 L/kg. Protein binding is approximately 50% and the drug shows no preferential partitioning into red blood cells. Flumazenil is a highly extracted drug. Clearance of flumazenil occurs primarily by hepatic metabolism and is dependent on hepatic blood flow. In pharmacokinetic studies of normal volunteers, total clearance ranges from 0.7 to 1.3 L/hr/kg, with less than 1% of the administered dose eliminated unchanged in the urine. The major metabolites of flumazenil identified in urine are the de-ethylated free acid and its glucuronide conjugate. In preclinical studies there was no evidence of pharmacologic activity exhibited by the de-ethylated free acid. Elimination of radiolabelled drug is essentially complete within 72 hours, with 90% to 95% of the radioactivity appearing in urine and 5% to 10% in the feces.

Pharmacokinetic Parameters Following a 5-minute Infusion of a total of 1.0 mg of MAZICON Mean (Coefficient of variation, Range)

C_{max} (ng/mL)	24 (38%, 11-43)
AUC (ng•hr/mL)	15 (22%, 10-22)
V_{ss} (L/kg)	1 (24%, 0.8-1.6)
Cl (L/hr/kg)	1 (20%, 0.7-1.4)
Half-life (min)	54 (21%, 41-79)

The pharmacokinetics of flumazenil are not significantly affected by gender, age, renal failure (creatinine clearance <10 mL/min), or hemodialysis beginning 1 hour after drug administration. Mean total clearance is decreased to 40% to 60% of normal in patients with moderate liver dysfunction and to 25% of normal in patients with severe liver dysfunction compared with age-matched healthy subjects. This results in a prolongation of the half-life from 0.8 hours in healthy subjects to 1.3 hours in patients with moderate hepatic impairment and 2.4 hours in severely impaired patients. Ingestion of food during an intravenous infusion of the drug results in a 50% increase in clearance, most likely due to the increased hepatic blood flow that accompanies a meal. The pharmacokinetic profile of flumazenil is unaltered in the presence of benzodiazepine agonists and the kinetic profiles of those benzodiazepines are unaltered by flumazenil.

CLINICAL TRIALS: MAZICON has been administered to reverse the effects of benzodiazepines in conscious sedation, general anesthesia, and the management of suspected benzodiazepine overdose.
CONSCIOUS SEDATION: MAZICON was studied in four trials in 970 patients who received an average of 30 mg diazepam or 10 mg midazolam for sedation (with or without a narcotic) in conjunction with both inpatient and outpatient diagnostic or surgical procedures. MAZICON was effective in reversing the sedating and psychomotor effects of the benzodiazepine, however, amnesia was less completely and less consistently reversed. In these studies, MAZICON was administered as an initial dose of 0.4 mg I.V. (two doses of 0.2 mg) with additional 0.2 mg doses as needed to achieve complete awakening, up to a maximum total dose of 1.0 mg. Seventy-eight percent of patients receiving flumazenil responded by becoming completely alert. Of those patients, approximately half responded to doses of 0.4 to 0.6 mg, while the other half responded to doses of 0.8 to 1.0 mg. Adverse effects were infrequent in patients who received 1 mg of MAZICON or less, although injection site pain, agitation and anxiety did occur. Reversal of sedation was not associated with any increase in the frequency of inadequate analgesia or increase in narcotic demand in these studies. While most patients remained alert throughout the 3 hour post-procedure observation period, resedation was observed to occur in 3% to 9% of the patients, and was most common in patients who had received high doses of benzodiazepine. (See PRECAUTIONS.)
GENERAL ANESTHESIA: MAZICON was studied in four trials in 644 patients who received midazolam as an induction and/or maintenance agent in both balanced and inhalational anesthesia. Midazolam was generally administered in doses ranging from 5 to 80 mg, alone and/or in conjunction with muscle relaxants, nitrous oxide, regional or local anesthetics, narcotics and/or inhalational anesthetics. Flumazenil was given as an initial dose of 0.2 mg IV, with additional 0.2 mg doses as needed to reach a complete response, up to a maximum total dose of 1.0 mg. These doses were effective in reversing sedation and restoring psychomotor function, but did not completely restore memory as tested by picture recall. MAZICON was not as effective in the reversal of sedation in patients who had received multiple anesthetic agents in addition to benzodiazepines.
Eighty-one percent of patients sedated with midazolam responded to flumazenil by becoming completely alert or just slightly drowsy. Of those patients, 36% responded to doses of 0.4 to 0.6 mg, while 64% responded to doses of 0.8 to 1.0 mg.
Resedation in patients who responded to MAZICON occurred in 10% to 15% of patients studied and was more common with larger doses of midazolam (>20 mg), long procedures (>60 minutes) and use of neuromuscular blocking agents. (See PRECAUTIONS.)
MANAGEMENT OF SUSPECTED BENZODIAZEPINE OVERDOSE: MAZICON was studied in two trials in 497 patients who were presumed to have taken an overdose of a benzodiazepine, either alone or in combination with a variety of other agents. In these trials, 299 patients were proven to have taken a benzodiazepine as part of the overdose, and 80% of the 148 who received MAZICON responded by an improvement in level of consciousness. Of the patients who responded to flumazenil, 75% responded to a total dose of 1.0 to 3.0 mg. Reversal of sedation was associated with an increased frequency of symptoms of CNS excitation. Of the

patients treated with flumazenil, 1% to 3% were treated for agitation or anxiety. Serious side effects were uncommon, but six seizures were observed in 446 patients treated with flumazenil in these studies. Four of these 6 patients had ingested a large dose of cyclic antidepressants, which increased the risk of seizures. (See WARNINGS.)

INDIVIDUALIZATION OF DOSAGE: GENERAL PRINCIPLES: The serious adverse effects of MAZICON are related to the reversal of benzodiazepine effects. Using more than the minimally effective dose of MAZICON is tolerated by most patients but may complicate the management of patients who are physically dependent on benzodiazepines or patients who are depending on benzodiazepines for therapeutic effect (such as suppression of seizures in cyclic antidepressant overdose).
In high-risk patients, it is important to administer the smallest amount of MAZICON that is effective. The 1-minute wait between individual doses in the dose-titration recommended for general clinical populations may be too short for high risk patients. This is because it takes 6 to 10 minutes for any single dose of flumazenil to reach full effects. Practitioners should slow the rate of administration of MAZICON administered to high risk patients as recommended below.
ANESTHESIA AND CONSCIOUS SEDATION: MAZICON is well tolerated at the recommended doses in individuals who have no tolerance to (or dependence on) benzodiazepines. The recommended dosages and titration rates in anesthesia and conscious sedation (0.2 to 1.0 mg given at 0.2 mg/min) are well tolerated in patients receiving the drug for reversal of a single benzodiazepine exposure in most clinical settings (see Adverse Events). The major risk will be resedation because the duration of effect of a long-acting (or large dose of a short-acting) benzodiazepine may exceed that of MAZICON. Resedation may be treated by giving a repeat dose at no less than 20-minute intervals. For repeat treatment, no more than 1.0 mg (at 0.2 mg/min doses) should be given at any one time and no more than 3.0 mg should be given in any one hour.
OVERDOSE PATIENTS: The risk of confusion, agitation, emotional lability and perceptual distortion with the doses recommended in patients with benzodiazepine overdose (3 to 5 mg administered as 0.5 mg/min) may be greater than that expected with lower doses and slower administration. The recommended doses represent a compromise between a desirable slow awakening and the need for prompt response and a persistent effect in the overdose situation. If circumstances permit, the physician may elect to use the 0.2 mg/minute titration rate to slowly awaken the patient over 5 to 10 minutes, which may help to reduce signs and symptoms on emergence.
MAZICON has no effect in cases where benzodiazepines are not responsible for sedation. Once doses of 3 to 5 mg have been reached without clinical response, additional MAZICON is likely to have no effect.
PATIENTS TOLERANT TO BENZODIAZEPINES: MAZICON may cause benzodiazepine withdrawal symptoms in individuals who have been taking benzodiazepines long enough to have some degree of tolerance. Patients who had been taking benzodiazepines prior to entry into the MAZICON trials who were given flumazenil in doses over 1 mg experienced withdrawal-like events 2 to 5 times more frequently than patients who received less than 1 mg.
In patients who may have tolerance to benzodiazepines, as indicated by clinical history or by the need for larger than usual doses of benzodiazepine, slower titration rates of 0.1 mg/min and lower total doses may help reduce the frequency of emergent confusion and agitation. In such cases special care must be taken to monitor the patients for resedation because of the lower doses of MAZICON used.
PATIENTS PHYSICALLY DEPENDENT ON BENZODIAZEPINES: MAZICON is known to precipitate withdrawal seizures in patients who are physically dependent on benzodiazepines, even if such dependence was established in a relatively few days of high dose sedation in Intensive Care Unit environments. The risk of either seizures or resedation in such cases is high and patients have experienced seizures before regaining consciousness. MAZICON should be used in such settings with extreme caution, since the use of flumazenil in this situation has not been studied and no information as to dose and rate of titration is available. MAZICON should be used in such patients only if the potential benefits of using the drug outweigh the risks of precipitated seizures. Physicians are directed to the scientific literature for the most current information in this area.

INDICATIONS AND USAGE: MAZICON is indicated for the complete or partial reversal of the sedative effects of benzodiazepines in cases where general anesthesia has been induced and/or maintained with benzodiazepines, where sedation has been produced with benzodiazepines for diagnostic and therapeutic procedures, and for the management of benzodiazepine overdose.

CONTRAINDICATIONS: MAZICON is contraindicated:
- In patients with a known hypersensitivity to flumazenil or to benzodiazepines.
- In patients who have been given a benzodiazepine for control of a potentially life-threatening condition (*e.g.* control of intracranial pressure or status epilepticus).
- In patients who are showing signs of serious cyclic antidepressant overdose. (See WARNINGS.)

WARNINGS:

THE USE OF MAZICON HAS BEEN ASSOCIATED WITH THE OCCURRENCE OF SEIZURES.
THESE ARE MOST FREQUENT IN PATIENTS WHO HAVE BEEN ON BENZODIAZEPINES FOR LONG-TERM SEDATION OR IN OVERDOSE CASES WHERE PATIENTS ARE SHOWING SIGNS OF SERIOUS CYCLIC ANTIDEPRESSANT OVERDOSE.
PRACTITIONERS SHOULD INDIVIDUALIZE THE DOSAGE OF MAZICON AND BE PREPARED TO MANAGE SEIZURES.

Risk of Seizures: The reversal of benzodiazepine effects may be associated with the onset of seizures in certain high-risk populations. Possible risk factors for seizures include: concurrent major sedative-hypnotic drug withdrawal, recent therapy with repeated doses of parenteral benzodiazepines, myoclonic jerking or seizure activity prior to flumazenil administration in overdose cases, or concurrent cyclic antidepressant poisoning.
MAZICON is not recommended in cases of serious cyclic antidepressant poisoning, as manifested by motor abnormalities (twitching, rigidity, focal seizure), dysrhythmia (wide QRS, ventricular dysrhythmia, heart block), anticholinergic signs (mydriasis, dry mucosa, hypo-peristalsis), and cardiovascular collapse at presentation. In such cases MAZICON should be withheld and the patient should be allowed to remain sedated (with ventilatory and circulatory support as needed) until the signs of antidepressant toxicity have subsided. Treatment with MAZICON has no known benefit to the seriously ill mixed-overdose patient other than reversing sedation and should not be used in cases where seizures (from any cause) are likely.
Most convulsions associated with flumazenil administration require treatment and have been successfully managed with benzodiazepines, phenytoin or barbiturates. Because of the presence of flumazenil, higher than usual doses of benzodiazepines may be required.

HYPOVENTILATION: Patients who have received MAZICON for the reversal of benzodiazepine effects (after conscious sedation or general anesthesia) should be monitored for resedation, respiratory depression, or other residual benzodiazepine effects for an appropriate period (up to 120 minutes) based on the dose and duration of effect of the benzodiazepine employed.
This is because MAZICON has not been established as an effective treatment for hypoventilation due to benzodiazepine administration. The availability of flumazenil does not diminish the need for prompt detection of hypoventilation and the ability to effectively intervene by establishing an airway and assisting ventilation.
MAZICON may not fully reverse postoperative airway problems or ventilatory insufficiency induced by benzodiazepines. In addition, even if MAZICON is initially effective, such problems may recur because the effects of MAZICON wear off before the effects of many benzodiazepines.
Overdose cases should always be monitored for resedation until the patients are stable and resedation is unlikely.

PRECAUTIONS: RETURN OF SEDATION: MAZICON may be expected to improve the alertness of patients recovering from a procedure involving sedation or anesthesia with benzodiazepines, but should not be substituted for an adequate period of post-procedure monitoring. The availability of MAZICON does not reduce the risks associated with the use of large doses of benzodiazepines for sedation.
Patients should be monitored for resedation, respiratory depression (see WARNINGS), or other persistent or recurrent agonist effects for an adequate period of time after administration of MAZICON.
Resedation is least likely in cases where MAZICON is administered to reverse a low dose of a short-acting benzodiazepine (<10 mg midazolam). It is most likely in cases where a large single or cumulative dose of a benzodiazepine has been given in the course of a long procedure along with neuromuscular blocking agents and multiple anesthetic agents.
Profound resedation was observed in 1% to 3% of patients in the clinical studies. In clinical situations where resedation must be prevented, physicians may wish to repeat the initial dose (up to 1 mg of MAZICON given at 0.2 mg/min) at 30 minutes and possibly again at 60 minutes. This dosage schedule, although not studied in clinical trials, was effective in preventing resedation in a pharmacologic study in normal volunteers.
USE IN THE ICU: MAZICON should be used with caution in the Intensive Care Unit because of the increased risk of unrecognized benzodiazepine dependence in such settings. MAZICON may produce convulsions in patients physically dependent on benzodiazepines. (See INDIVIDUALIZATION OF DOSAGE AND WARNINGS.)
Administration of MAZICON to diagnose benzodiazepine-induced sedation in the Intensive Care Unit is not recommended due to the risk of adverse events as described above. In addition, the prognostic significance of a patient's failure to respond to flumazenil in cases confounded by metabolic disorder, traumatic injury, drugs other than benzodiazepines, or any other reasons not associated with benzodiazepine receptor occupancy is not known.

USE IN OVERDOSE: MAZICON is intended as an adjunct to, not as a substitute for, proper management of airway, assisted breathing, circulatory access and support, internal decontamination by lavage and charcoal, and adequate clinical evaluation.

Necessary measures should be instituted to secure airway, ventilation and intravenous access prior to administering flumazenil. Upon arousal patients may attempt to withdraw endotracheal tubes and/or intravenous lines as the result of confusion and agitation following awakening.

HEAD INJURY: MAZICON should be used with caution in patients with head injury as it may be capable of precipitating convulsions or altering cerebral blood flow in patients receiving benzodiazepines. It should be used only by practitioners prepared to manage such complications should they occur.

USE WITH NEUROMUSCULAR BLOCKING AGENTS: MAZICON should not be used until the effects of neuromuscular blockade have been fully reversed.

USE IN PSYCHIATRIC PATIENTS: MAZICON has been reported to provoke panic attacks in patients with a history of panic disorder.

PAIN ON INJECTION: To minimize the likelihood of pain or inflammation at the injection site, MAZICON should be administered through a freely flowing intravenous infusion into a large vein. Local irritation may occur following extravasation into perivascular tissues.

USE IN RESPIRATORY DISEASE: The primary treatment of patients with serious lung disease who experience serious respiratory depression due to benzodiazepines should be appropriate ventilatory support (See PRECAUTIONS) rather than the administration of MAZICON. Flumazenil is capable of partially reversing benzodiazepine-induced alterations in ventilatory drive in healthy volunteers, but has not been shown to be clinically effective.

USE IN CARDIOVASCULAR DISEASE: MAZICON did not increase the work of the heart when used to reverse benzodiazepines in cardiac patients when given at a rate of 0.1 mg/min in total doses of less than 0.5 mg in studies reported in the clinical literature. Flumazenil alone had no significant effects on cardiovascular parameters when administered to patients with stable ischemic heart disease.

USE IN LIVER DISEASE: The clearance of MAZICON is reduced to 40% to 60% of normal in patients with mild to moderate hepatic disease and to 25% of normal in patients with severe hepatic dysfunction. (See PHARMACOKINETICS.) While the dose of flumazenil used for initial reversal of benzodiazepine effects is not affected, repeat doses of the drug in liver disease should be reduced in size or frequency.

USE IN DRUG AND ALCOHOL DEPENDENT PATIENTS: MAZICON should be used with caution in patients with alcoholism and other drug dependencies due to the increased frequency of benzodiazepine tolerance and dependence observed in these patient populations.

MAZICON is not recommended either as a treatment for benzodiazepine dependence or for the management of protracted benzodiazepine abstinence syndromes, as such use has not been studied.

The administration of flumazenil can precipitate benzodiazepine withdrawal in animals and man. This has been seen in healthy volunteers treated with therapeutic doses of oral lorazepam for up to 2 weeks who exhibited effects such as hot flushes, agitation and tremor when treated with cumulative doses of up to 3 mg doses of flumazenil.

Similar adverse experiences suggestive of flumazenil precipitation of benzodiazepine withdrawal have occurred in some patients in clinical trials. Such patients had a short-lived syndrome characterized by dizziness, mild confusion, emotional lability, agitation (with signs and symptoms of anxiety), and mild sensory distortions. This response was dose-related, most common at doses above 1 mg, rarely required treatment other than reassurance and was usually short lived. When required (5 to 10 cases), these patients were successfully treated with usual doses of a barbiturate, a benzodiazepine, or other sedative drug.

Practitioners should assume that flumazenil administration may trigger dose-dependent withdrawal syndromes in patients with established physical dependence on benzodiazepines and may complicate the management of withdrawal syndromes for alcohol, barbiturates and cross-tolerant sedatives.

DRUG INTERACTIONS: Interaction with central nervous system depressants other than benzodiazepines has not been specifically studied; however, no deleterious interactions were seen when MAZICON was administered after narcotics, inhalational anesthetics, muscle relaxants and muscle relaxant antagonists administered in conjunction with sedation or anesthesia.

Particular caution is necessary when using MAZICON in cases of mixed drug overdosage since the toxic effects (such as convulsions and cardiac dysrhythmias) of other drugs taken in overdose (especially cyclic antidepressants) may emerge with the reversal of the benzodiazepine effect by flumazenil. (See WARNINGS.)

The pharmacokinetics of benzodiazepines are unaltered in the presence of flumazenil.

USE IN AMBULATORY PATIENTS: The effects of MAZICON may wear off before a long-acting benzodiazepine is completely cleared from the body. In general, if a patient shows no signs of sedation within 2 hours after a 1.0 mg dose of flumazenil, serious resedation at a later time is unlikely. An adequate period of observation must be provided for any patient in whom either long-acting benzodiazepines (such as diazepam) or large doses of short-acting benzodiazepines (such as >10 mg of midazolam) have been used. (See INDIVIDUALIZATION OF DOSAGE.)

Because of the increased risk of adverse reactions in patients who have been taking benzodiazepines on a regular basis, it is particularly important that physicians query carefully about benzodiazepine, alcohol and sedative use as part of the history prior to any procedure in which the use of MAZICON is planned. (See DRUG AND ALCOHOL DEPENDENT PATIENTS.)

INFORMATION FOR PATIENTS: MAZICON does not consistently reverse amnesia. Patients cannot be expected to remember information told to them in the post-procedure period and instructions given to patients should be reinforced in writing or given to a responsible family member. Physicians are advised to discuss with their patients, both before surgery and at discharge, that although the patient may feel alert at the time of discharge, the effects of the benzodiazepine may recur. As a result, the patient should be instructed, preferably in writing, that their memory and judgment may be impaired and specifically advised:

1. Not to engage in any activities requiring complete alertness, and not to operate hazardous machinery or a motor vehicle until at least 18 to 24 hours after discharge, and it is certain no residual sedative effects of the benzodiazepine remain.
2. Not to take any alcohol or non-prescription drugs for 18 to 24 hours after flumazenil administration or if the effects of the benzodiazepine persist.

LABORATORY TESTS: No specific laboratory tests are recommended to follow the patient's response or to identify possible adverse reactions.

DRUG/LABORATORY TEST INTERACTIONS: The possible interaction of flumazenil with commonly used laboratory tests has not been evaluated.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: No studies in animals to evaluate the carcinogenic potential of flumazenil have been conducted.

Mutagenesis: No evidence for mutagenicity was noted in the Ames test using five different tester strains. Assays for mutagenic potential in *S. cerevisiae* D7 and in Chinese hamster cells were considered to be negative as were blastogenesis assays *in vitro* in peripheral human lymphocytes and *in vivo* in a mouse micronucleus assay. Flumazenil caused a slight increase in unscheduled DNA synthesis in rat hepatocyte culture at concentrations which were also cytotoxic; no increase in DNA repair was observed in male mouse germ cells in an *in vivo* DNA repair assay.

Impairment of fertility: A reproduction study in male and female rats did not show any impairment of fertility at oral dosages of 125 mg/kg/day. From the available data on the area under the curve (AUC) in animals and man the dose represented 120 x the human exposure from a maximum recommended intravenous dose of 5 mg.

PREGNANCY: CATEGORY C. There are no adequate and well-controlled studies of the use of flumazenil in pregnant women. Flumazenil should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Teratogenic Effects: Flumazenil has been studied for teratogenicity in rats and rabbits following oral treatments of up to 150 mg/kg/day. The treatments during the major organogenesis were on days 6 to 15 of gestation in the rat and days 6 to 18 of gestation in the rabbit. No teratogenic effects were observed in rats or rabbits at 150 mg/kg; the dose, based on the available data on the area under the plasma concentration-time curve (AUC) represented 120 x to 600 x the human exposure from a maximum recommended intravenous dose of 5 mg in humans. In rabbits, embryocidal effects (as evidenced by increased pre-implantation and post-implantation losses) were observed at 50 mg/kg or 200 x the human exposure from a maximum recommended intravenous dose of 5 mg. The no-effect dose of 15 mg/kg in rabbits represents 60 x the human exposure.

Nonteratogenic Effects: An animal reproduction study was conducted in rats at oral dosages of 5, 25 and 125 mg/kg/day of flumazenil. Pup survival was decreased during the lactating period, pup liver weight at weaning was increased for the high-dose group (125 mg/kg/day) and incisor eruption and ear opening in the offspring were delayed; the delay in ear opening was associated with a delay in the appearance of the auditory startle response. No treatment-related adverse effects were noted for the other dose groups. Based on the available data from AUC, the effect level (125 mg/kg), represents 120 x the human exposure from 5 mg, the maximum recommended intravenous dose in humans. The no-effect level represents 24 x the human exposure from an intravenous dose of 5 mg.

LABOR AND DELIVERY: The use of MAZICON to reverse the effects of benzodiazepines used during labor and delivery is not recommended because the effects of the drug in the newborn are unknown.

NURSING MOTHERS: Caution should be exercised when deciding to administer MAZICON to a nursing woman because it is not known whether flumazenil is excreted in human milk.

PEDIATRIC USE: MAZICON is not recommended for use in children (either for the reversal of sedation, the management of overdose or the resuscitation of the newborn), as no clinical studies have been performed to determine the risks, benefits and dosages to be used.

GERIATRIC USE: The pharmacokinetics of flumazenil have been studied in the elderly and are not significantly different from younger patients. Several studies of MAZICON in patients over the age of 65 and one study in patients over the age of 80 suggest that while the doses of benzodiazepine used to induce sedation should be reduced, ordinary doses of MAZICON may be used for reversal.

ADVERSE REACTIONS: SERIOUS ADVERSE REACTIONS: Deaths have occurred in patients who received MAZICON in a variety of clinical settings. The majority of deaths occurred in patients with serious underlying disease or in patients who had ingested large amounts of non-benzodiazepine drugs, (usually cyclic antidepressants) as part of an overdose.

Serious adverse events have occurred in all clinical settings, and convulsions are the most common serious adverse event reported. MAZICON administration has been associated with the onset of convulsions in patients who are relying on benzodiazepine effects to control seizures, are physically dependent on benzodiazepines, or who have ingested large doses of other drugs. (See WARNINGS.)

Two of the 446 patients who received MAZICON in controlled clinical trials for the management of a benzodiazepine overdosage had cardiac dysrhythmias (1 ventricular tachycardia, 1 junctional tachycardia).

ADVERSE EVENTS IN CLINICAL STUDIES: The following adverse reactions were considered to be related to MAZICON administration (both alone and for the reversal of benzodiazepine effects) and were reported in studies involving 1875 individuals who received flumazenil in controlled trials. Adverse events most frequently associated with flumazenil alone were limited to dizziness, injection site pain, increased sweating, headache and abnormal or blurred vision (3% to 9%).

BODY AS A WHOLE: Fatigue (asthenia, malaise), Headache, Injection Site Pain*, Injection Site Reaction (thrombophlebitis, skin abnormality, rash)

CARDIOVASCULAR SYSTEM: Cutaneous vasodilation (sweating, flushing, hot flushes)

DIGESTIVE SYSTEM: Nausea and Vomiting (11%)

NERVOUS SYSTEM: Agitation (anxiety, nervousness, dry mouth, tremor, palpitations, insomnia, dyspnea, hyperventilation)*, Dizziness (vertigo, ataxia) (10%), Emotional lability (crying abnormal, depersonalization, euphoria, increased tears, depression, dysphoria, paranoia).

SPECIAL SENSES: Abnormal Vision (visual field defect, diplopia), Paresthesia (sensation abnormal, hypoesthesia)

All adverse reactions occurred in 1% to 3% of cases unless otherwise marked.

*indicates reaction in 3% to 9% of cases.

Observed percentage reported if greater than 9%.

The following adverse events were observed infrequently (less than 1%) in the clinical studies, but were judged as probably related to MAZICON administration and/or reversal of benzodiazepine effects:

NERVOUS SYSTEM: Confusion (difficulty concentrating, delirium), Convulsions (see WARNINGS), Somnolence (stupor).

SPECIAL SENSES: Abnormal Hearing (transient hearing impairment, hyperacusis, tinnitus).

The following adverse events occurred with frequencies less than 1% in the clinical trials. Their relationship to MAZICON administration is unknown, but they are included as alerting information for the physician.

BODY AS A WHOLE: Rigors, shivering.

CARDIOVASCULAR: Arrhythmia (atrial, nodal, ventricular extrasystoles), bradycardia, tachycardia, hypertension, chest pain.

DIGESTIVE SYSTEM: Hiccup.

NERVOUS SYSTEM: Speech disorder (dysphonia, thick tongue).

Not included in this list is operative site pain that occurred with the same frequency in patients receiving placebo as in patients receiving flumazenil for reversal of sedation following a surgical procedure.

DRUG ABUSE AND DEPENDENCE: MAZICON acts as a benzodiazepine antagonist, blocks the effects of benzodiazepines in animals and man, antagonizes benzodiazepine reinforcement in animal models, produces dysphoria in normal subjects, and has had no reported abuse in foreign marketing.

Although MAZICON has a benzodiazepine-like structure it does not act as a benzodiazepine agonist in man and is not a controlled substance.

OVERDOSAGE: Large intravenous doses of MAZICON, when administered to healthy normal volunteers in the absence of a benzodiazepine agonist, produced no serious adverse reactions, severe signs or symptoms, or clinically significant laboratory test abnormalities. In clinical studies, most adverse reactions to flumazenil were an extension of the pharmacologic effects of the drug in reversing benzodiazepine effects.

Reversal with an excessively high dose of MAZICON may produce anxiety, agitation, increased muscle tone, hyperesthesia and possibly convulsions. Convulsions have been treated with barbiturates, benzodiazepines and phenytoin, generally with prompt resolution of the seizures. (See WARNINGS.)

DOSE AND ADMINISTRATION: MAZICON is recommended for intravenous use only. It is compatible with 5% dextrose in water, lactated Ringer's and normal saline solutions. If MAZICON is drawn into a syringe or mixed with any of these solutions, it should be discarded after 24 hours. For optimum sterility, MAZICON should remain in the vial until just before use. As with all parenteral drug products, MAZICON should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

To minimize the likelihood of pain at the injection site, MAZICON should be administered through a freely running intravenous infusion into a large vein.

REVERSAL OF CONSCIOUS SEDATION OR IN GENERAL ANESTHESIA: For the reversal of the sedative effects of benzodiazepines administered for conscious sedation or general anesthesia, the recommended initial dose of MAZICON is 0.2 mg (2 mL) administered intravenously over 15 seconds. If the desired level of consciousness is not obtained after waiting an additional 45 seconds, a further dose of 0.2 mg (2 mL) can be injected and repeated at 60-second intervals where necessary (up to a maximum of 4 additional times) to a maximum total dose of 1 mg (10 mL). The dose should be individualized based on the patient's response, with most patients responding to doses of 0.6 to 1 mg. (See INDIVIDUALIZATION OF DOSAGE.)

In the event of resedation, repeated doses may be administered at 20 minute intervals as needed. For repeat treatment, no more than 1 mg (given as 0.2 mg/min) should be administered at any one time, and no more than 3 mg should be given in any one hour.

It is recommended that MAZICON be administered as the series of small injections described (not as a single bolus injection) to allow the practitioner to control the reversal of sedation to the approximate endpoint desired and to minimize the possibility of adverse effects. (See INDIVIDUALIZATION OF DOSAGE.)

MANAGEMENT OF SUSPECTED BENZODIAZEPINE OVERDOSE: For initial management of a known or suspected benzodiazepine overdose, the recommended initial dose of MAZICON is 0.2 mg (2 mL) administered intravenously over 30 seconds. If the desired level of consciousness is not obtained after waiting 30 seconds, a further dose of 0.3 mg (3 mL) can be administered over another 30 seconds. Further doses of 0.5 mg (5 mL) can be administered over 30 seconds at 1-minute intervals up to a cumulative dose of 3 mg.

Do not rush the administration of MAZICON. Patients should have a secure airway and intravenous access before administration of the drug and be awakened gradually. (See PRECAUTIONS.)

Most patients with benzodiazepine overdose will respond to a cumulative dose of 1-3 mg of MAZICON, and doses beyond 3 mg do not reliably produce additional effects. On rare occasions, patients with a partial response at 3 mg may require additional titration up to a total dose of 5 mg (administered slowly in the same manner).

If a patient has not responded 5 minutes after receiving a cumulative dose of 5 mg MAZICON, the major cause of sedation is likely not to be due to benzodiazepines, and additional MAZICON is likely to have no effect.

In the event of resedation, repeated doses may be given at 20-minute intervals if needed. For repeat treatment, no more than 1 mg (given as 0.5 mg/min) should be given at any one time and no more than 3 mg should be given in any one hour.

SAFETY AND HANDLING: MAZICON is supplied in sealed dosage forms and poses no known risk to the health care provider. Routine care should be taken to avoid aerosol generation when preparing syringes for injection, and spilled medication should be rinsed from the skin with cool water.

HOW SUPPLIED: 5 mL multiple-use vials containing 0.1 mg/mL flumazenil:
Boxes of 10 (NDC 0004-6904-14).
10 mL multiple-use vials containing 0.1 mg/mL flumazenil:
Boxes of 10 (NDC 0004-6905-14).
Store at 59° to 86° F (15° to 30° C).

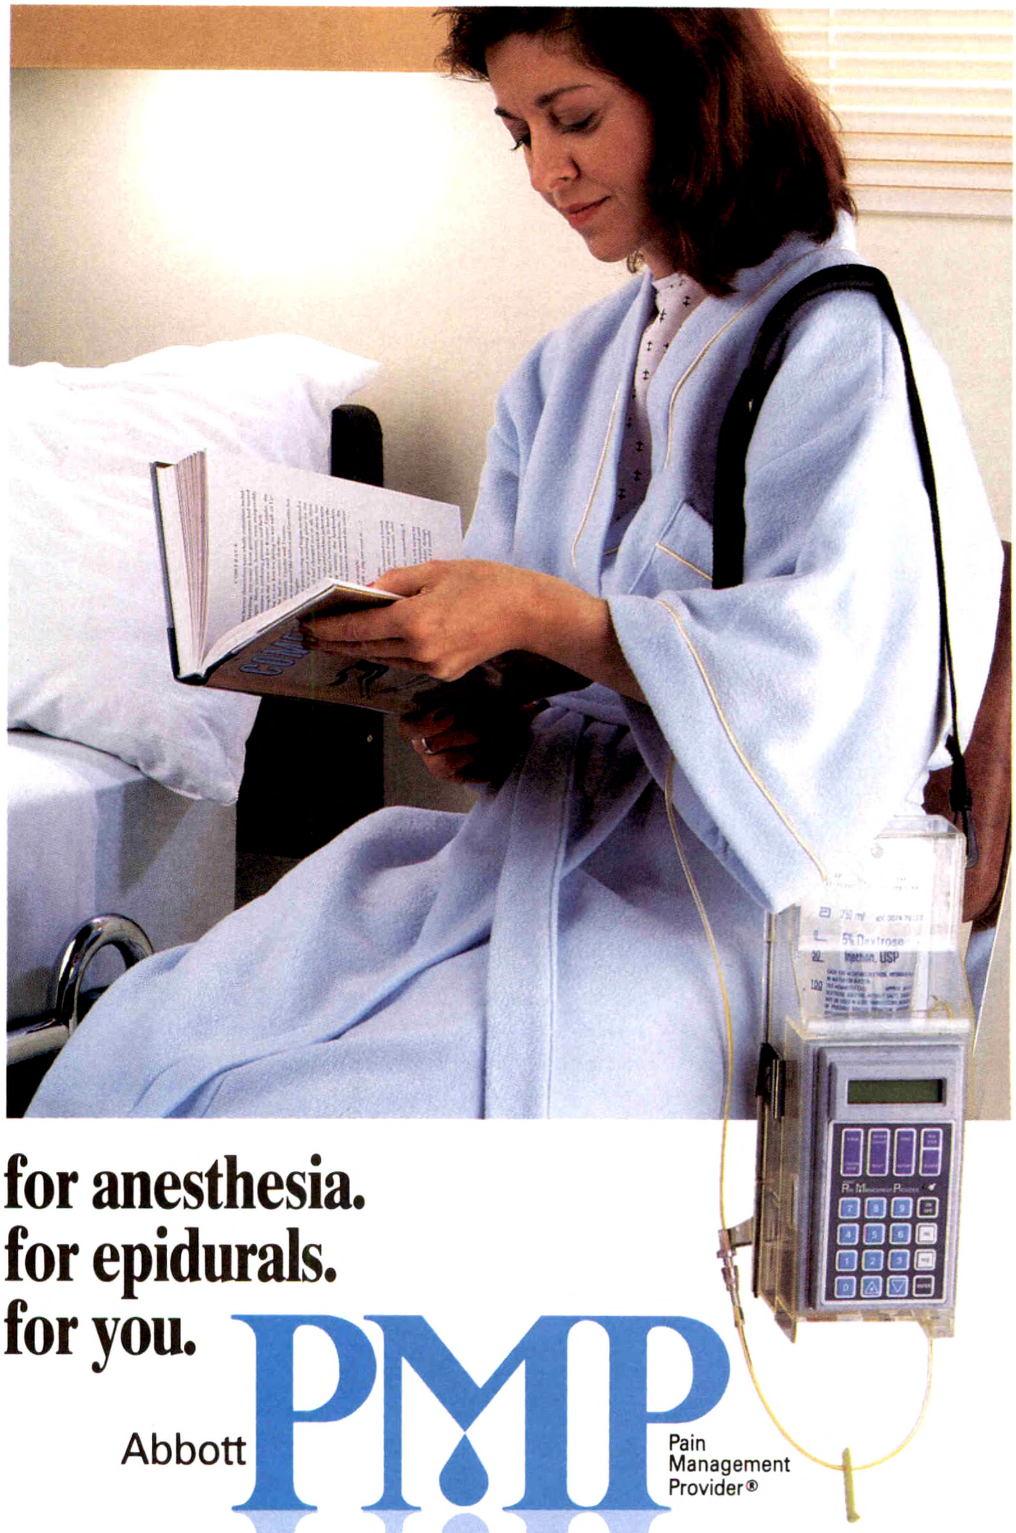
ABBOTT ANESTHESIA



Designed for anesthesia.
Designed for epidurals.
Designed for you.

Abbott PMP
Pain
Management
Provider®

© 1992, Abbott Laboratories

Because Abbott PMP makes it easier

by creating a dedicated, epidural programming sequence so intuitive it practically eliminates physician in-servicing.

Because a dedicated system makes it better

by devoting a *single* infusion device for a *single* infusion procedure. Abbott PMP for epidurals helps eliminate errors, minimizes disposables inventory, and makes every epidural procedure easier for everyone.

Because it is what you expect from a leader in anesthesiology

Abbott offers the industry's most extensive line of anesthesia devices, drugs, administration sets, and epidural trays available. And that means unparalleled system compatibility and standardization, simplified inventory and ordering, product support, and single-source technical assistance.

Look into Abbott PMP.

Designed just for you and your patients

Abbott Laboratories
Hospital Products Division
North Chicago, Illinois 60064

The Abbott Pain Management Provider® Infusion System is recognized as a device for the administration of epidural anesthesia and analgesia. This indication is for short-term postsurgical epidural administration, not to exceed 96 hours, of the anesthetics lidocaine hydrochloride and chloroprocaine hydrochloride and the analgesic morphine sulphate injection preservative free.

Caution: Federal (USA) law prohibits dispensing without prescription.

Nitrous Oxide Impairs Functional Recovery of Stunned Myocardium in Barbiturate-Anesthetized, Acutely Instrumented Dogs

Daniel Siker, MD, Paul S. Pagel, MD, Lorie R. Pelc, PhD, John P. Kampine, MD, PhD, William T. Schmeling, MD, PhD, and David C. Warltier, MD, PhD

Departments of Anesthesiology, Pharmacology, and Medicine, Medical College of Wisconsin; Zablocki Veterans Administration Medical Center; and Children's Hospital of Wisconsin, Milwaukee, Wisconsin

The purpose of this investigation was to characterize the effects of nitrous oxide or nitrogen (70%) on systemic and regional hemodynamics and myocardial tissue perfusion after a brief coronary artery occlusion (15 min) and reperfusion (3 h). Two groups of experiments (14 experiments total) were completed with 24 open-chest, barbiturate-anesthetized dogs. Coronary collateral blood flow was diverted from the ischemic zone during coronary artery occlusion to eliminate a source of variability in degree of ischemia produced by differences in degrees of collateral blood flow among animals. Seven of 16 dogs treated with nitrous oxide and 7 of 8 dogs treated with nitrogen survived coronary occlusion and reperfusion ($P < 0.05$). Coronary artery occlusion produced paradoxical systolic bulging in the ischemic zone in both groups of experiments. After reperfusion, segment shortening gradually returned toward control levels but remained depressed from the preocclusion state after 3 h in the nitrogen-treated control group. Similar results were observed after reperfusion in the nitrous oxide group; however, segment function in the ischemic region was significantly ($P < 0.05$) depressed throughout the 3-h reperfusion period compared with the control group. Transmural coronary collateral blood flow during occlusion was not significantly different ($P > 0.05$) between groups, indicating that differences in recovery of contractile function observed between groups could not be attributed to differences in myocardial oxygen supply. In addition, the similarity in systemic hemodynamics between the nitrous oxide and control groups indirectly suggests that differences in recovery of function could not be attributed to differences in myocardial oxygen demand. The results indicate that 70% nitrous oxide produces greater mortality after coronary artery occlusion and reperfusion and reduces functional recovery of postischemic, reperfused myocardium compared with 70% nitrogen in open-chest, acutely instrumented dogs.

(Anesth Analg 1992;75:539–48)

Reperfusion after brief periods of coronary artery occlusion is associated with delayed recovery of contractile function despite return of blood flow to normal levels (1). This reversible postischemic myocardial dysfunction, termed "stunned" myocardium (2), may be prolonged but occurs without tissue necrosis (3,4). This phenomenon appears to play an important role in the natural history of ischemic heart disease because spontaneous reperfusion of ischemic myocardium after thrombosis or coronary vasospasm is known to occur frequently in patients with coronary artery disease. In addition, patients with acute myocardial ischemia often undergo coronary artery reperfusion through interventions, such as thrombolytic therapy, angioplasty, and emergency bypass surgery, in attempts to salvage myocardium at risk.

The pathogenesis of stunned myocardium remains unclear despite extensive study (3). Although tissue reperfusion is necessary to preserve myocardial integrity, several ischemia-induced cellular abnormalities have been implicated in the subsequent development of reperfusion injury (1,3–7). Intracellular calcium overload (8), depletion of high-energy phosphates (9–11), production of oxygen-derived free radicals (12,13), and uncoupling of myocyte excitation and contraction (14) have all been suggested as contributing etiologies for the contractile dysfunction observed in stunned myocardium. Pharmacologic

therapy has focused on modulation of these diverse pathophysiologic abnormalities and a variety of treatment modalities, including calcium channel blockers (15–18), vasodilators (15,19), β-adrenergic antagonists (20), specific bradycardic agents (21), and superoxide dismutase and catalase (22), have all been shown to enhance recovery.

The effects of anesthetics on contractile function recovery in postischemic, reperfused myocardium have been examined only recently. Volatile anesthetics have been shown to improve functional recovery of stunned myocardium when these agents are administered in vivo (23) and in vitro (24) before and during, but not after (25), brief periods of myocardial ischemia. The effects of nitrous oxide on stunned myocardium have not been previously described. Use of this anesthetic gas in patients with ischemic heart disease remains controversial. Studies in experimental models of coronary artery constriction have suggested that nitrous oxide may contribute to development of myocardial ischemia (26–31). Most clinical investigations have been unable to confirm these findings in patients with coronary artery disease (32–38). Accordingly, systemic and coronary hemodynamics, regional contractile function, and intramyocardial blood flow, as evaluated by the radioactive microsphere technique, were recorded during brief coronary artery occlusion (15 min) and 3 h of reperfusion in control (70% nitrogen) and nitrous oxide (70%) groups. Because dogs have varying degrees of coronary collateral circulation, retrograde coronary flow was diverted during occlusion to eliminate the variability of endogenous collateral blood flow among animals. The present investigation was performed to characterize actions of nitrous oxide on recovery of function of stunned myocardium in open-chest, barbiturate-anesthetized dogs.

Methods

Experimental Preparation

All experimental procedures and protocols used in this investigation were reviewed and approved by the Animal Care Committee of the Medical College of Wisconsin. Furthermore, all conformed to the *Guiding Principles in the Care and Use of Animals* of the American Physiologic Society and were in accordance with the *Guide for the Care and Use of Laboratory Animals* (DHEW [DHHS] publication No. [NIH] 85-23, revised 1985).

Twenty-four adult male and female mongrel dogs, weighing 25–30 kg, were fasted overnight and anesthetized with sodium pentobarbital (25 mg/kg) and sodium barbital (200 mg/kg). After tracheal intubation, ventilation was controlled (Ohio Medical Products, Airco Inc., Madison, Wis.) with an oxygen (30%)–nitrogen (70%) mixture (1.0 L/min). Respiratory rate and tidal volume were adjusted to maintain arterial blood gases within normal physiologic limits (pH 7.35–7.45; P_{CO_2} 30–35 mm Hg; P_{O_2} 85–100 mm Hg). Temperature was monitored and maintained at 37° ± 1°C (mean ± SE) by a humidified circuit, warming light, and heating pad connected to a servomechanical controller.

Dual-pressure transducer-tipped catheters (SPR-277, Millar, Houston, Tex.) were placed into the left ventricle and ascending aorta through the left carotid artery for measurement of continuous left ventricular and arterial pressures, respectively. Peak positive dP/dt, an index of global left ventricular contractility, was obtained by electronic differentiation of the left ventricular pressure pulse. A triangular wave signal of known slope was used to calibrate the differentiator. The right femoral vein and left femoral artery were catheterized for fluid administration and for withdrawal of reference arterial blood samples, respectively. A thoracotomy was performed at the left fifth intercostal space. The lung was gently retracted, and the heart was suspended in a pericardial cradle. A catheter was placed in the left atrium through the atrial appendage for injection of radioactive microspheres. The right carotid artery was isolated and cannulated. A 1.0–1.5-cm segment of the left anterior descending coronary artery (LAD) was isolated distal to the first diagonal branch and cannulated with a large-bore, metal-tipped catheter. Heparin (300 U/kg) was administered intravenously. Perfusion to the distal LAD was reestablished within 2 min after cannulation via a silastic shunt from the right carotid artery. A cannulating electromagnetic flow probe (Statham SP7515, Gould Instruments, Cleveland, Ohio) for measurement of coronary blood flow was placed proximal to a side arm in the shunt with a three-way stopcock. The stopcock was suspended at the level of the heart and used for passive diversion of coronary collateral blood flow during coronary artery occlusion. A steel clamp was positioned around the silastic shunt immediately distal to the flow probe for production of coronary artery occlusion. The site of LAD cannulation was chosen so that approximately equal regions of the left ventricle were subjected to ischemia in all animals. The mass of the left ventricle subjected to occlusion and reperfusion was 27.7% ± 1.0% (mean ± SE) of the total left ventricular mass in all dogs.

Myocardial contractile function (percent segment shortening [%SS]) was measured in the ischemic (LAD) and normal (left circumflex coronary artery [LCCA]) regions with ultrasonic segment-length transducers (5 MHz) implanted (10–15 mm apart and 7–9 mm deep) into the subendocardium of each region parallel to fiber orientation. Segment-length signals were monitored and driven by an ultrasonic amplifier (Hartley, Houston, Tex.). End-systolic segment length (ESL) was determined at maximal negative dP/dt, and end-diastolic segment length (EDL) was determined at the onset of left ventricular isovolumetric contraction. The lengths were normalized according to the method described by Theroux et al. (39). Percent segment shortening was calculated using the following equation: $\%SS = (EDL - ESL) \times 100/EDL$. All hemodynamic data were continuously recorded on a polygraph (model 7, Grass Instrument Co., Quincy, Mass.).

At the end of each experiment, the heart was electrically fibrillated, immediately removed, and fixed in 10% formaldehyde for 24–48 h. India ink (5 mL) was injected distally through the LAD cannula to darken the area of myocardium subjected to coronary occlusion and reperfusion. The left ventricle and septum was separated from the remainder of the heart, divided into stained and unstained regions, and weighed to determine the mass of the left ventricle subjected to ischemic insult.

Regional Tissue Perfusion

Carbonized plastic microspheres (15 ± 2 μm in diameter) (New England Nuclear, Boston, Mass.) labeled with ^{141}Ce, ^{103}Ru, ^{51}Cr, or ^{95}Nb were used to measure regional tissue perfusion (40). Immediately before injection, the sphere suspension was ultrasonicated (E/MC Corporation, model 450) for 15 min and agitated in a vortex mixer (Cole-Parmer, model 4722) for 5 min. The microsphere injection consisted of approximately 2–3 $\times 10^6$ spheres injected into the left atrial chamber as a bolus dose over 10 s and flushed in with 10 mL of warm (37°C) sterile saline solution. A few seconds before each microsphere injection, a timed collection of reference arterial blood from the femoral arterial catheter was initiated and maintained at a constant rate of 7 mL/min for 3 min (precalibrated Harvard infusion/withdrawal pump, model 1941).

At the conclusion of each experiment, transmural myocardial tissue samples were selected for mapping of regional myocardial blood flow. The samples were subdivided into subepicardial, midmyocardial, and subendocardial layers of approximately equal thickness. Samples were weighed, placed in scintillation vials, and the activity of each isotope was determined. The activity of each isotope in the reference blood samples was also determined. The radioactivity in the tissue and reference blood samples was analyzed with a gamma counter (Minaxi 5000, Packard, Downers Grove, Ill.). Myocardial blood flow (Q_m) ($mL \cdot min^{-1} \cdot g^{-1}$) was calculated from the following equation: $Q_m = Q_r \cdot C_m / C_r$, where Q_r is the rate of withdrawal of the reference blood flow sample (mL/min), C_r is the activity (counts per minute [cpm]) of the reference blood flow sample, and C_m is the activity (cpm/g) of the tissue sample.

Experimental Protocol

Dogs were assigned to receive either nitrous oxide (70%) or nitrogen (70%) in combination with oxygen (30%) before and during LAD occlusion in a random fashion in separate experimental groups. After surgery was completed, the preparation was allowed to stabilize for 30 min during ventilation with room air enriched with oxygen (30%). Control hemodynamics and regional contractile function were then recorded, and a radioactive microsphere injection was completed. Hemodynamics and regional myocardial blood flow were again measured after a 30-min period of equilibration during administration of nitrous oxide (70%) or nitrogen (70%) in oxygen (30%). End-tidal gases were continuously measured by mass spectrometry (Advantage 2000, Marquette Electronics, St. Louis, Mo.). The LAD flow was then interrupted for 15 min by the mechanical occluder in both groups. During LAD occlusion, retrograde LAD coronary flow from the cannulas was allowed to drain by gravity to reduce collateral perfusion within the ischemic zone. After 12 min of LAD occlusion, hemodynamics and segment function were measured, and another set of radioactive microspheres was administered. The occlusion was removed after 15 min, and reperfusion was allowed to occur. All dogs (in both control [nitrogen] and nitrous oxide groups) received lidocaine (1 mg/kg IV) and procainamide (5 mg/kg IV) immediately before reperfusion. Nitrous oxide (70%) or nitrogen (70%) was continued throughout the occlusion and 15 min into the reperfusion period in separate groups. Nitrous oxide was then discontinued, and room air enriched with oxygen (30%) was reinstituted. Hemodynamics and regional myocardial function were recorded at 5, 15, 30, 60, 120, and 180 min during the reperfusion period. A final set of radioactive microspheres was administered at the completion of the 3-h reperfusion period. Thus, systemic hemodynamics, regional myocardial function, and myocardial tissue perfusion before and during acute coronary artery occlusion and during 3 h of reperfusion were studied in control (70% nitrogen) and nitrous oxide (70%)-exposed groups. Twenty-four dogs were used to provide seven experiments in each group.

Statistical Analysis

Statistical analysis of data within and between groups before and during coronary artery occlusion and reperfusion was performed using analysis of variance

[a] Significantly ($P < 0.05$) different from preocclusion control values.

(ANOVA) with repeated measures, followed by application of Bonferroni's modification of the t-test. Changes from control within and between groups were considered statistically significant when the probability (P) value was <0.05. Mortality data between groups were compared with the χ^2 analysis. All data are expressed as mean ± SE.

Results

Twenty-four dogs were used to provide 14 complete stun and reperfusion experiments. Seven of 8 dogs in the control group but only 7 of 16 nitrous oxide-treated dogs survived reperfusion ($P < 0.05$). All deaths were caused by ventricular fibrillation occurring during reperfusion despite prophylactic administration of lidocaine or procainamide. Systemic and coronary hemodynamics during coronary artery occlusion and reperfusion in control experiments are summarized in Table 1. Occlusion of the LAD was accompanied by significant ($P < 0.05$) decreases in heart rate, mean arterial pressure, left ventricular systolic pressure, rate-pressure product, and left ventricular peak positive dP/dt. Significantly ($P < 0.05$) increased left ventricular end-diastolic pressure was observed during acute coronary artery occlusion. These hemodynamic variables recovered to preocclusion levels 30–60 min after the start of reperfusion. Mean LAD blood flow was reduced to zero during occlusion. After a brief reactive hyperemia during the first 5 min of reperfusion, mean coronary blood flow was not statistically different from preocclusion control during the remaining reperfusion period. Occlusion of the LAD resulted in a significant ($P < 0.05$) decrease in percent segment shortening (from 19.5% ± 3.3% during the preocclusion control to −3.3% ± 1.5% during coronary occlusion), indicating regional contractile dysfunction. The paradoxical passive lengthening observed during the period of coronary occlusion in the LAD region was reversed by reperfusion, but segment shortening remained depressed from preocclusion levels throughout the 3-h reperfusion period (Figure 1). No significant changes in segment shortening occurred during occlusion or reperfusion in the normal (LCCA) region (Figure 2).

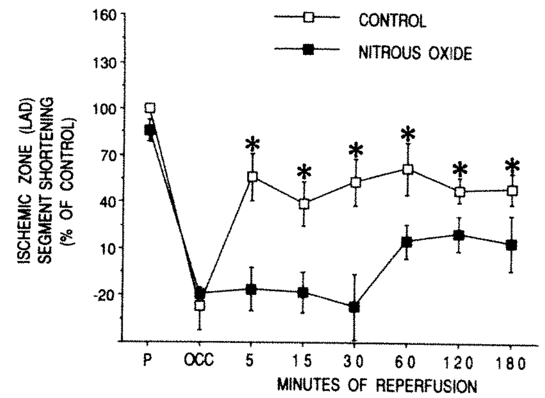

Figure 1. Ischemic zone segment shortening data (mean ± SE) before coronary artery occlusion (P), during occlusion (OCC), and at various times after reperfusion in control and nitrous oxide groups. *Significantly ($P < 0.05$) different from respective time point in the nitrous oxide group. LAD, left anterior descending coronary artery.

Systemic and coronary hemodynamics in nitrous oxide experiments are summarized in Table 2. Administration of 70% nitrous oxide produced significant ($P < 0.05$) increases in mean arterial pressure and left ventricular systolic pressure. The LAD coronary occlusion caused significant ($P < 0.05$) decreases

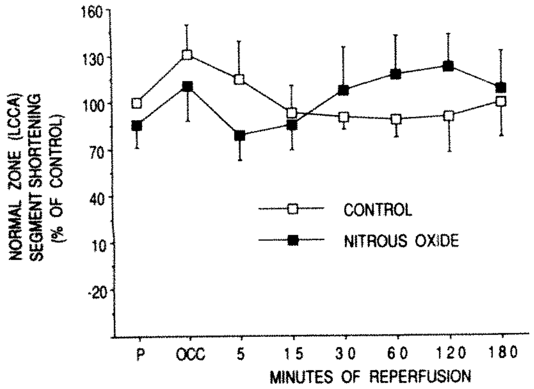

Figure 2. Normal zone segment shortening data (mean ± SE) before coronary artery occlusion (P), during occlusion (OCC), and at various times after reperfusion in control and nitrous oxide groups. LCCA, left circumflex coronary artery.

in heart rate, mean arterial pressure, left ventricular systolic pressure, rate-pressure product, and dP/dt from the 70% nitrous oxide state. A significant increase in left ventricular end-diastolic pressure was also observed during coronary artery occlusion. As was observed in the control experiments, a brief reactive hyperemia was noted immediately after LAD reperfusion in the presence of nitrous oxide; mean coronary blood flow in the LAD remained constant and not statistically different from the preocclusion levels during the remainder of the reperfusion period. Systolic shortening was replaced by paradoxical passive lengthening during coronary occlusion in the nitrous oxide group. In contrast to the control experiments, passive lengthening persisted during the first 30 min of reperfusion. In addition, the depression of regional contractile function observed in the LAD region after coronary reperfusion in nitrous oxide-treated dogs was significantly greater than that observed in the control experiments throughout reperfusion (Figure 1). As was observed in control experiments, no changes in segment shortening occurred in the normal (LCCA) region (Figure 2).

Regional myocardial perfusion assessed by radioactive microspheres before, during, and after coronary occlusion in both control and nitrous oxide experiments is summarized in Table 3. The LAD occlusion with diversion of retrograde flow produced severe reductions in blood flow to ischemic zone subepicardium, midmyocardium, and subendocardium. Total blood flow approached 0 $mL \cdot min^{-1} \cdot g^{-1}$ in the occluded vessel perfusion territory, indicating little if any coronary collateral flow to the ischemic zone. No changes in transmural perfusion were noted in the normal region in either group. Administration of nitrous oxide before coronary occlusion did not alter subepicardial, midmyocardial, and subendocardial perfusion when compared with preocclusion control in either the LAD or LCCA regions. As observed in control experiments, LAD occlusion resulted in transmural reduction in regional myocardial perfusion in the occluded vessel perfusion territory. No changes were observed in the normal region (LCCA). Reperfusion resulted in the return of myocardial blood flow to preocclusion levels in subendocardial, midmyocardial, and subepicardial regions of the LAD perfusion territory.

Discussion

Although nitrous oxide effects on myocardial function with normal coronary circulation have been well characterized, controversy remains as to its use in patients with ischemic heart disease. Philbin et al. (26) demonstrated in dogs that nitrous oxide added to an opioid-based anesthetic may produce contractile dysfunction (evaluated by appearance of postsystolic shortening) in myocardium perfused by a stenotic coronary artery. Ramsey et al. (27) confirmed these findings and demonstrated that the addition of nitrous oxide to halothane also resulted in global and regional contractile dysfunction in an identical model. Leone et al. (28) identified a dose-response relationship for this phenomenon and suggested that regional dysfunction in myocardium supplied by a critically narrowed coronary artery occurred when nitrous oxide was administered at inspired concentrations as low as 40%. Substitution of 50% nitrous oxide for 0.4% isoflurane produced a reduction in ventricular function and maldistribution of blood flow to ischemic myocardium in open-chest, acutely instrumented dogs in an investigation by Nathan (29). The same investigator (41) later reported that nitrous oxide effects on ischemic myocardium could be explained by systemic hemodynamic actions and direct depression of contractile function independent of direct coronary effects. Wilkowski et al. (30) demonstrated that 60% nitrous oxide produced significant constriction of epicardial coronary arteries assessed by angiography but did not alter coronary arteriolar tone, as evaluated by ^{133}Xe washout technique. The data suggested that nitrous oxide had differential effects on coronary vasculature, and these authors (30) speculated that epicardial coronary vasoconstriction produced by nitrous oxide may precipitate further blood supply decreases to myocardium distal to a stenosis. More recently, Pettis et al. (31) demonstrated in pigs that nitrous oxide produced epicardial coronary artery constriction in vivo by an endothelium-derived constricting-factor mechanism.

Although some evidence supports the contention that nitrous oxide may result in development of

myocardial ischemia in experimental models of coronary disease, clinical studies examining the effects of nitrous oxide in patients with ischemic heart disease have not verified this conclusion. Nitrous oxide has been shown to decrease myocardial contractility when administered alone (32,33) or in combination with opioids (34,35) to patients with coronary artery disease, but no evidence of new ischemia occurred, indirectly suggesting that nitrous oxide was not producing clinically significant effects. Using more specific ischemia indicators, others have shown that nitrous oxide added to another anesthetic does not precipitate myocardial ischemia in susceptible patients. Cahalan et al. (36) examined ST segment changes and segmental left ventricular function with either nitrous oxide or nitrogen in patients undergoing coronary bypass graft surgery. No ST segment alterations or regional wall motion abnormalities were observed with the introduction of nitrous oxide, suggesting that it did not produce myocardial ischemia when used with fentanyl during anesthesia. Mitchell et al. (37) performed a similar study in patients with coronary artery disease and impaired left ventricular function. These investigators found that nitrous oxide did not cause clinically detectable ischemia and did not exacerbate global left ventricular dysfunction (37). Regional wall motion abnormalities evaluated by two-dimensional transesophageal echocardiography in patients anesthetized with sufentanil for coronary bypass surgery before cardiopulmonary bypass were also not detected during exposure to 70% nitrous oxide when compared with 70% nitrogen (38). Thus, although some evidence exists to suggest that nitrous oxide may contribute to regional contractile dysfunction in experimental models of coronary artery obstruction, these concerns have not been clinically demonstrated.

Persistent regional contractile dysfunction after blood flow has been restored to transiently ischemic myocardium has been extensively characterized (1–6,10). Spontaneous coronary artery reperfusion after thrombus formation or spasm is a clinically recognized phenomenon that occurs frequently in patients with coronary artery disease. This dynamic process represents an important part of the natural history of coronary artery disease. Interventions, such as thrombolytic therapy, angioplasty, or coronary artery bypass graft surgery, used to reestablish coronary blood flow in the management of acute ischemia may also be associated with development of stunned myocardium. Although the magnitude of postischemic dysfunction is primarily determined by duration and severity of ischemic insult (1,4,5), ischemia and subsequent reperfusion produce a cascade of events possibly responsible for subsequent reperfusion injury (6,7).

Although a number of potential mechanisms have been suggested, the etiology of contractile dysfunction in postischemic, reperfused myocardium remains unclear. Several studies (9–11,42) have shown that high-energy phosphate levels are depressed and recover in a time-course that parallels the functional recovery of stunned myocardium. The assertion that inadequate postischemic adenosine triphosphate levels are responsible for the slow recovery of regional contractile function is not without controversy (16,43–45). Production of oxygen-derived free radicals, either by ischemic myocytes or by infiltrating neutrophils with reperfusion-supplied oxygen, may be important mediators in the production of postischemic contractile dysfunction (12,13,46–48). Other factors, including intracellular calcium overload (8,43,49), myocyte excitation-contraction uncoupling (14), abnormalities in cardiac sympathetic neural responsiveness (50), and myocyte edema (51), have also been implicated.

Pharmacologic interventions directed toward improvement of postischemic, reperfused myocardial performance have focused on modulation of these abnormalities. Calcium channel antagonists significantly enhance functional recovery of stunned myocardium by controlling elevations of intracellular calcium and by reducing myocardial oxygen demand and decreasing severity of ischemia during coronary artery occlusion (15–18). Scavenging of oxygen-derived free radicals with superoxide dismutase and catalase enhances the recovery of stunned myocardium (22). Decreased myocardial oxygen consumption during the ischemic event induced by β-adrenergic antagonists (20), specific bradycardic agents (21), and vasodilators (15,19) may reduce high-energy phosphate catabolism and lead to more rapid recovery of contractile function. More recently, a monoclonal antibody directed against a neutrophil-derived adhesion protein was effective in improving functional outcome after brief myocardial ischemia (47), providing a potential immunologic treatment option, and emphasizing that neutrophil migration and activation (48) may also play a critical role in the development of reperfusion-induced contractile dysfunction.

The actions of volatile anesthetics on stunned myocardium recovery have recently been examined. Freedman et al. (24) reported that enflurane improved functional recovery of stunned myocardium in isolated rat hearts. An investigation from this laboratory (23) demonstrated that recovery of contractile function of postischemic, reperfused myocardium is enhanced by halothane or isoflurane when these agents are administered to chronically instrumented dogs before or during 15 min of total coronary artery occlusion. This protective effect of inhaled anesthetics was attributed to improvement in the oxygen supply-demand balance, coupled with calcium influx blockade by voltage-dependent slow channels (52,53) and stimulation of calcium uptake into the sarcoplasmic reticulum (54,55). Administration of halothane and isoflurane during reperfusion rather than before and during ischemia did not enhance function recovery of stunned myocardium when these volatile anesthetics were delivered (25).

The present investigation indicates that 70% nitrous oxide impairs functional recovery of postischemic, reperfused myocardium compared with 70% nitrogen control. Administration of nitrous oxide before and during coronary occlusion led to significantly greater mortality secondary to ventricular fibrillation. The mechanisms by which nitrous oxide depressed recovery of stunned myocardium and increased mortality are unknown. Before occlusion, nitrous oxide increased mean arterial and left ventricular systolic pressures. The rate-pressure product, an indirect indicator of myocardial oxygen demand, numerically increased, although this change did not reach statistical significance. Although myocardial oxygen consumption was not specifically measured, these alterations indirectly suggest that a greater imbalance in the myocardial oxygen supply-demand relationship may represent a potential mechanism by which nitrous oxide increases ischemia severity during coronary occlusion, thereby reducing recovery of function. Sympathetic nerve stimulation (56) and increased norepinephrine release (57) during nitrous oxide may have contributed to this process, although serum catecholamines were not specifically obtained in the present investigation. Nitrous oxide produces direct negative inotropic effects in vivo (58) and in vitro (59). Depression of myocardial contractility should improve functional recovery of stunned myocardium by decreasing myocardial oxygen consumption during the ischemic episode. However, nitrous oxide-induced sympathetic nervous system stimulation may mask these direct reductions in contractile function (60) and therefore negate possible protective effects of direct decreases in contractility. Reductive metabolism of nitrous oxide to free radical intermediates in certain anaerobic environments could represent a theoretical mechanism by which this agent may impair functional recovery of postischemic, reperfused myocardium (61). Constriction of epicardial coronary arteries, possibly mediated by increased sympathetic tone during nitrous oxide, could also decrease myocardial oxygen supply (30,31). Although epicardial coronary artery diameter was not specifically measured in the present study, there were no changes in transmural coronary blood flow assessed by radiolabeled microspheres in either ischemic or nonischemic zones with nitrous oxide, suggesting that intramyocardial blood flow alterations were not responsible for differences observed in the functional recovery of stunned myocardium.

Barbiturate anesthesia used in this investigation is commonly used in open-chest dog preparations and offers the advantage of hemodynamic stability over a prolonged time-course without the requirement of repeated dosing or anesthetic adjuvants. In addition, the time-course of functional recovery of postischemic, reperfused myocardium is similar in conscious and barbiturate-anesthetized dogs despite significantly different systemic hemodynamic profiles (62). In contrast, volatile anesthetics significantly enhance the functional recovery of stunned myocardium (23,24), a finding that may complicate interpretation of the effects of nitrous oxide on postischemic reperfusion injury. Clearly, however, the use of a pure barbiturate anesthetic in the absence of opioids or other anesthetic adjuvants is useful only for an experimental preparation, and results of this investigation must be interpreted within the constraints of this anesthetic regimen.

In summary, 70% nitrous oxide significantly reduced functional recovery of postischemic, reperfused myocardium and resulted in significantly greater mortality when compared with 70% nitrogen in barbiturate-anesthetized, open-chest dogs. Extension of the findings of this investigation to clinical settings should be approached with caution. The results indicate that the time-course of recovery of stunned myocardium is further delayed by nitrous oxide.

The authors thank Jeanne Howard and David Schwabe for their technical assistance and Mimi Mick and Suzanne Emmrich for their help in the preparation of this manuscript.

Fertilization and Mouse Embryo Development in the Presence of Midazolam

R. James Swanson, PhD, and Maria G. Leavitt, MS

Department of Biological Sciences, Old Dominion University, Norfolk, Virginia

Mouse embryo in vitro development elucidates the effect of a pharmacologic agent on cellular differentiation. Midazolam provides conscious sedation for patients undergoing egg retrieval for in vitro fertilization and is found in patient follicular fluid. Mouse preimplantation embryo formation and development were evaluated in the presence of midazolam. Midazolam was cocultured with two-cell mouse preimplantation embryos over 72 h and injected systemically just before ovulation and coitus. Concentrations to 12.5 μg/mL displayed no significant toxic effects on in vitro two-cell-to-blastocyst development. Doses to 35.0 mg/kg did not prevent or impair in vivo fertilization. Midazolam has no adverse effect on in vitro development of two-cell-to-blastocyst-stage embryos nor on in vivo fertilization and cell division at concentrations approximating and exceeding those that ova are exposed to during clinical anesthesia. Midazolam is recommended for use to induce sedation in human in vitro fertilization where association with gametes and zygotes is probable.

(Anesth Analg 1992;75:549–54)

Mouse embryo culturing was initiated in the Embryonics Laboratory at Old Dominion University in 1980 as a quality-control screening assay for media, supplements, culture ware, and related equipment used in developing the human in vitro fertilization program in Norfolk, Virginia (1–5). The mouse system was used to screen potential toxic effects of anesthetics used in egg retrieval for in vitro fertilization (IVF). Midazolam doses of 0.070–0.080 mg/kg were used for intravenous induction of anesthesia in IVF. We administered a total of approximately 0.07 mg/kg of midazolam to seven patients who were undergoing egg retrieval. Midazolam concentrations ranging from 17.7 to <1 ng/mL were found in follicular fluid samples after ova retrieval from the seven patients (unpublished data). Eggs from all seven patients fertilized at a rate of 94% (29/31); there were two of seven (29%) biochemical pregnancies, and of those two, one of seven (14%) term pregnancies (unpublished data). For this sample size, fertilization and pregnancy rates are within acceptable limits. Research into the potential toxic effects of midazolam was prompted by these observations. Mouse zygote formation and early preembryo development were used as a model to test midazolam.

Methods

Mice

The experimental protocol was submitted and approved by the University Animal Use and Care Committee. Embryos used in this study were obtained from hybrid B_6CBA F_1 ($C57Bl_6 \times CBA$) virgin female mice (purchased from the Jackson Laboratory, Bar Harbor, Me.) crossed with outbred CD-1 males 3–10 mo old (Charles River Laboratories, Wilmington, Del.). Unlike many strains, this F_2 hybrid mouse strain has proved to produce consistently high numbers of embryos with 100% development to the blastula stage in 72 h if all culturing variables are at an optimum (3). Mice were 4–6 wk old when received and acclimated to our animal facility before use. All mice were used within 12 wk of purchase. Mice were maintained on a lighting regime of 14 h light, 10 h dark (lights on at 5 AM) at 21°–24°C and were given laboratory rodent chow (Ralston Purina, St. Louis, Mo.) and water ad libitum. Euthanasia was by cervical dislocation, approved by the Panel on Euthanasia of the American Veterinary Medical Association.

Supported in part by a grant from The Embryonics Laboratory, Old Dominion University, Norfolk, Virginia.

Accepted for publication May 11, 1992.

Superovulation and Mating

Female mice selected at random with regard to estrous were induced to superovulate by intraperitoneal (IP) injections of 5 IU of pregnant mare serum gonadotropin (Sigma Chemical Co., St. Louis, Mo.) followed 48 h later by 5 IU of human chorionic gonadotropin (hCG) (Sigma). At hCG injection time, each female mouse was placed in a cage with one proved fertile male CD-1 mouse. Both injections were given between 4 and 6 PM. Female mice go into estrous and mate within 6 h after hCG injection, with ovulation occurring between 10 and 13 h after hCG injection. Between 9 and 10 AM on the following morning, female mice were inspected for vaginal plugs and the results of the males' copulatory performances were recorded. Any male failing to produce a copulation plug after more than three consecutive weeks was culled from the colony.

Collection of Embryos

Plug-positive females were sequentially killed by cervical dislocation over a period of 2 h starting approximately 42 h after the hCG injection. The abdomen of the mouse cadaver was entered by tearing a small hole over the umbilicus and then stripping the skin simultaneously down over the hindlegs and up over the forelegs. This technique leaves a completely sterile field without any mouse hair and obviates the use of antiseptic agents that can compromise embryo viability. The rectus abdominis was severed 2–3 mm superior to the symphysis pubis, continuing the incision bilaterally up each flank to the ribs. Oviducts were excised by first gently stretching/tearing the mesosalpinx and mesometrium close to each oviduct and uterine horn, respectively, and then cutting between the oviduct and ovary at the intramural junction with microsurgical scissors (No. ST-SAS-15, ASSI, Accurate Scientific & Surgical Instruments, Westbury, N.Y.). Three pairs of oviducts were placed in each sterile 35 × 10-mm polystyrene Nunclon culture dish (Thomas Scientific, Swedesboro, N.J.) containing 2 mL of modified Krebs-Ringer-bicarbonate (mKRB) medium. Under a Ziess dissecting stereomicroscope (Eastern Microscope Co., Raleigh, N.C.) at 20× magnification, watchmaker forceps (ASSI, No. ST-JFC-7) were used to slide the swollen infundibulum onto a 30-gauge (B-D, Becton Dickinson, Baxter Diagnostics Inc., Scientific Products Division, Columbia, Md.) sterile needle attached to a 1-mL sterile syringe (B-D). Embryos were washed from the oviducts with medium lightly expressed from the syringe. Groups of five normal (judged by oval, bilateral symmetry of the two blastomeres with narrow perivitelline space and presence of two small polar bodies) two-cell embryos were evaluated at 32× magnification and collected from the petri dish with a 10-μL Eppendorf (Microliter Pipetters, Fisher Scientific, Norcross, Ga.) micropipette fitted with a sterile tip and dispensed into flat-sided culture tubes containing 1.0 mL of medium per tube (110 × 16-mm Nunclon flat-sided, screw-top tissue culture tubes, Thomas Scientific). At least five embryos from each mouse were cultured in a tube containing control medium. Each test medium was evaluated in triplicate cultures.

Media

Media used was mKRB solution supplemented with 4 mg bovine serum albumin per milliliter (1). After composition, media was checked for a pH value between 7.6 and 7.8 (before CO_2 equilibration); filter-sterilized into 150-mL, red-necked, 0.22-μm filter units (type TC, Nalge Company, Division of Sybron Corp., Rochester, N.Y.), dispensed into the tissue culture tubes, and incubated at 37°C in 5% CO_2 in air for at least 18 h before use.

Midazolam

Midazolam HCl is commercially available as injectable Versed in 1-mL vials at 5 mg/mL or 5-mL vials at 1 mg/mL (Roche Products Inc., Nutley, N.J.). These vials contain the preservatives 0.01% disodium edetate and 1% benzyl alcohol in 0.8% aqueous NaCl. To facilitate dosage titration and minimize the preservative concentration, the 1-mL vial (5 mg/mL) of midazolam HCl was preferentially used.

In vitro response of embryo development to midazolam. Two-cell embryos were directly exposed to midazolam to determine the lowest dose completely inhibiting development to morula-plus-blastocyst stage after 72 h in culture. Subsequently, two-cell embryos were exposed to concentrations of midazolam below this lowest dose determined to totally inhibit development to morula or beyond.

Starting from 5-mg/mL concentrations of midazolam, solutions were prepared by dilution in mKRB medium to final concentrations of 500,000, 50,000, 25,000, 12,500, 5000, 500, 50, 25, 10, and 5 ng/mL. Use of the 5-mg/mL vial for making the most concentrated solutions results in 10 μL of Versed placed in 1 mL of mKRB medium. Therefore, in the most concentrated tube (500 μg/mL) of incubation medium, two-cell embryos would experience a final concentration of 0.0001% disodium edetate (1 μg/mL) and 0.01% benzyl alcohol (0.1 μL/mL) preservatives.

Table 1. Effects of Midazolam on the 72-h Culture of Two-Cell Mouse Embryos[a]

			Embryo stage					
Treatment	Midazolam (ng/mL)	Total two-cell embryos cultured	2 Cell	3–4 Cell	6–8 Cell	16–36 Cell	Morula + blastocyst	Degenerating embryos

[a] Two-cell embryos were coincubated in varying concentrations of midazolam to determine the lowest dose inhibiting development to morula-plus-blastocyst stages. Two-cell embryos were subsequently exposed to doses of midazolam below the minimal inhibitory dose. One-factor fixed-effects randomized block analysis of variation analysis of morula-plus-blastocyst development at 72 h in culture presented significant difference in higher concentrations (50,000 and 25,000 ng/mL) at $P < 0.005$ level. Lower concentrations allowed development. Furthermore, there were significant differences among treatments. Treatment A was equal to B. Treatments C, D, E, F, G, H, I, were equal and different from A.

Doses of midazolam inhibiting fertilization in vivo. Female mice were given an intraperitoneal injection of midazolam during the superovulation protocol immediately before the hCG injection. Midazolam doses for the mice were calculated from an equivalent dose administered during human ova harvesting: 0.070–0.080 mg/kg. Not only was an equivalent concentration used, but injections 5 (0.35 mg/kg), 40 (2.8 mg/kg), 100 (7.0 mg/kg), 200 (14.0 mg/kg), and 500 (35.0 mg/kg) times greater were given. Each midazolam solution, calculated for a 24-g mouse (weight ranged from 23 to 25 g), was administered in a constant volume of 0.1 mL. In the most concentrated intraperitoneal dose (35 mg/kg), a single mouse would receive approximately 100 ng of disodium edetate and 10 μL of benzyl alcohol.

Each female was placed with one male and checked within 12 h for a vaginal copulation plug. Approximately 42 h after hCG injection, two-cell embryos were collected. The presence of gametes or single-cell embryos, with absence of two-cell or later embryos, would indicate a midazolam-induced blocking or retardation of fertilization. Normal two-cell mouse embryos were collected if fertilization was not blocked or retarded and placed into culture media to observe normal development after 48 and 72 h.

Statistical Analysis

Development of two-cell mouse embryos to morula-plus-blastocyst stages after 72 h in culture was evaluated in both in vitro and in vivo experiments for (a) effect of midazolam in culture medium on embryo development and (b) effect of in vivo injection of midazolam into the female on embryo production and development. Data (Tables 1 and 2) were evaluated in a one-factor fixed-effects randomized block analysis of variance to test for overall significance among treatments, followed by Tukey's HSD (honestly significant difference) test to evaluate differences between specific treatments.

Results

Development of Two-Cell Mouse Embryo in Midazolam

Recovered two-cell mouse embryos were observed for development at 48 and 72 h. Various concentrations of midazolam were used in culture media, and their effects on embryo development after 72 h have been summarized in Table 1. One-hundred percent inhibition of morula-plus-blastocyst stage occurred with the two highest midazolam concentrations (50,000 and 25,000 ng/mL), but initial growth and cleavage beyond the two-cell stage was quantitatively different between these two concentrations. Sixty percent of the embryos were arrested at the two-cell stage with 50,000 ng/mL, whereas only 13% of the embryos were arrested at the two-cell stage with 25,000 ng/mL. Concentrations of midazolam ≤12,500 ng/mL did not display any significant toxic effects on morula-plus-blastocyst development (Table 1), with this development being >84% in all groups; however, there was an observable trend of reduced development in the 12,500–500-ng range (83%–88% morula-plus-blastocyst development). Control cultures of two-cell mouse embryos show a morula-plus-blastocyst development of 97% after 72 h in culture.

Table 2. In Vitro Two-Cell Mouse Embryo Development From Midazolam-Injected Dams

Midazolam dose (mg/kg)[a]	Total two-cell embryos recovered	Embryo stage					Degenerating cells
		2 Cell	3–4 Cell	6–8 Cell	16–32 Cell	Morula + blastocyst	
0.070	93	0	0	0	0	91 (97.8%)	2 (2.2%)
0.350	92	0	0	3 (3.2%)	9 (9.8%)	69 (74.2%)	11 (12.0%)
2.80	98	0	2 (2.0%)	0	2 (2.0%)	87 (89.0%	7 (7.2%)
7.0	104	5 (4.8%)	0	0	2 (2.0%)	92 (88.4%)	5 (4.8%)
14.0	72	0	0	0	0	71 (98.6%)	1 (1.3%)
35.0	95	0	0	0	0	93 (97.8%)	2 (2.1%)

Female mice were injected intraperitoneally with midazolam 48 h after pregnant mare serum gonadotropin and immediately before human chorionic gonadotropin injections. Two-cell embryos were observed for development at 72 h culture. One-factor fixed-effects randomized block analysis of variance analysis of two-cell mouse embryos development to morula-plus-blastocyst stage at 72 h in culture did not differ among treatments.

[a] Administered in a constant volume of 0.1 mL.

To arrive at a comparative midazolam toxicity value, percents were summed for embryos (a) demonstrating degeneration or fragmentation and (b) arrested at the two-cell stage after 72 h in culture. Midazolam concentrations of 50,000 ng/mL resulted in a toxic value of 76%, whereas concentrations of 25,000 ng/mL resulted in a toxic value of 58%.

In Vivo Fertilization After Midazolam Injection Into the Dam

Doses up to 500 times the human baseline dose produced no evidence that midazolam prevented or impaired in vivo fertilization. Normal two-cell mouse embryos were collected approximately 42 h after in vivo injection of midazolam in hCG (approximately 36 h after coitus). Development proceeded to control level percent of morula-plus-blastocyst stage after 72 h in culture (Table 2).

In several experiments, a low number of three- and four-cell embryos were collected along with two-cell embryos 42 h after midazolam and hCG injection. In comparison, control mice injected with pregnant mare serum gonadotropin and hCG rarely produced anything but two-cell embryos by this time.

Discussion

The in vitro culture of in vivo fertilized two-cell mouse embryos has been used routinely over the past 10 yr as a quality control of media and supplements of the Human IVF Program in Norfolk. One of the driving forces behind the use of the mouse embryo quality control has been the need to determine potential toxic effects of substances in contact with the human egg or culture media during egg retrieval and the in vitro fertilization process. Detection of midazolam in follicular fluid during human egg retrieval in the Norfolk Human IVF Program prompted this study. To rule out adverse effects of this anesthetic drug, mouse preimplantation embryos were fertilized and subsequently cultured in the presence of midazolam.

Results reported in this study came from two sets of experiments. In the first set, two-cell mouse embryos were cocultured in increasing concentrations of midazolam while their development was monitored. The Norfolk Human IVF Program washes the retrieved eggs twice and then places the ova in 3 mL of fresh media with 5 × 10^4 sperm/mL. Total time of midazolam exposure would never exceed 60 min, and in the seven cases where follicular fluid was studied, the concentration never exceeded 20 ng/mL. In these experiments, 72-h embryo coculture with midazolam without embryo washing exposed embryos to incremental concentrations of midazolam bracketing as well as exceeding that found in follicular fluids and also exceeding the time of exposure to this anesthetic. Midazolam did not produce any inhibitory effects on embryo development up to and including a concentration of 12,500 ng/mL (Table 1). A 0-ng/mL midazolam control was deemed trivial after initial pilot experiments showed no effect on embryo development at lowest doses. However, finding the level of disodium edetate and benzyl alcohol that arrests mouse embryo development to ensure that the effect observed at the higher doses was due to midazolam and not the preservative would have value. This work remains to be done.

The second set of experiments imitated the condition of human ova exposure to midazolam in follicular fluids during egg retrieval. Midazolam is a lipid-soluble drug that should be able to penetrate peritoneal membranes, follicular walls, and the unharvested ova. In this experiment, midazolam injected intraperitoneally into mice immediately before hCG injection (10–13 h before ovulation) did not impair fertilization. After intraperitoneal administration, midazolam in the ovary would undoubtedly achieve a lesser acme and have a more prolonged duration than the titration curve for ovarian midazolam after intravenous injection. Although achievable, tail vein injections in the mouse require either (a) pretranquilizing, which would be a confounding factor in testing midazolam, or (b) physical restraint with resultant large releases of thyroid-stimulating hormone and adrenocorticotropic hormone, which would have such wide ranging effects that variables and conclusions might be difficult to determine. Furthermore, absolute ovarian midazolam concentrations did not merit the challenge of discovery, but the goal was to establish the range within which midazolam would exert deleterious consequences. Midazolam was injected in incremental doses to determine the minimal inhibitory dose on in vivo fertilization. Doses up to 500-fold normal did not inhibit fertilization (Table 2) but were lethal in some cases. Significantly, in both sets of experiments, midazolam appeared to actually accelerate embryo development rather than inhibit it. In some experimental trials, blastocysts were observed after 48 h of growth in midazolam, compared with only morulae observed in control cultures. In dams injected with midazolam, collections of three- and four-cell embryos were often observed along with two-cell embryos, whereas control mice produced only two-cell embryos (unanalyzed observation). The embryo exists only on inherited material up to the mid-two-cell stage; many of the embryonic genes are switched on some time after the mid-two-cell stage (6). These observations suggested the possibility that the mitogenic activity of midazolam may increase DNA replication or translation. Excess storage of proteins and large numbers of copies of rRNA could account for the accelerated effect observed during the early cleavages of the embryos. Further studies will be necessary to determine the exact mechanism of midazolam action at the molecular level.

These experiments did not include studying the effects of midazolam on in vitro fertilization; however, because no inhibition was forthcoming on in vivo embryo production with overwhelming intraperitoneal doses, it seems valid to assume no effect of midazolam on in vitro fertilization. Nevertheless, it could be argued that the in vivo study of fertilization as described in this experiment may not reflect actual exposure to midazolam in follicles at a critical time in the maturation period of the ovum when it proceeds from prophase I to metaphase II, because the half-life of midazolam in the terminal elimination phase averages 1–4 h (7). In addition, although it has been assumed that serum concentrations of midazolam reflect follicular concentrations of midazolam, no direct measurement of midazolam in follicular fluid was performed in the mouse. Because the lipophilic nature of midazolam, and the fact that it was measured in human follicular fluid in the Norfolk Human IVF Program, a strong case exists for assuming its presence in the mouse follicle.

The mouse embryo system has advantages over the sea urchin for studying the mammalian fertilization process and embryo development. Effects of fentanyl on fertilization and early development of Echinodermata eggs were published by Bruce et al. in 1985. They reported that fentanyl in doses 7 and 14 times greater than the normal human dose did not inhibit fertilization in the sea urchin (8). Sea urchin division after fertilization is rapid, and a free-swimming, ciliated blastula results within 12 h. The process normally occurs in somewhat inconstant open seawater in a visible environment (8). In contrast, the mouse embryo divides slowly after fertilization, moving along the oviduct into the uterus for implantation 4.5 days after fertilization, all of which normally occurs in the highly constant and hidden in vivo environment. Despite this slower embryonic development, use of the mouse system permits an understanding of how genes control the growth and differentiation of the mammalian embryo (9). The mouse embryo system should be preferentially used for the screening of drugs. These experiments show that a drug can readily be tested for its effects on fertilization and embryo development.

In conclusion, these results indicate that recommended doses of midazolam have no inhibitory effects on fertilization and consequent embryo development to the blastocyst stage in mouse embryos. Clinical implications of these results reduce the uncertainty of potential inhibitory effects of midazolam during human egg retrieval. This study is the first to report the use of the mouse embryo system to evaluate the effects of anesthetic drugs on fertilization and early embryo development. Further expansion of these tests could include in vitro as well as in vivo fertilization, embryo transfer to surrogate females, implantation and placentation, and live birth. Longitudinal studies could give information on birth defects in second and third generations.

Skin Pretreatments for Shortening Onset of Dermal Patch Anesthesia With 3% GA MHPh 2Na–10% Lidocaine Gel Mixture

Tatsuhiko Kano, MD, PhD, Mari Nakamura, MD, Akira Hashiguchi, MD,
Michiaki Sadanaga, MD, Tohru Morioka, MD, PhD, Motohiro Mishima, PhD, and
Masahiro Nakano, PhD

Surgical Center, Departments of Anesthesiology and Pharmaceutical Service, Kumamoto University Hospital,
Kumamoto, Japan

Three types of skin pretreatments (stripping with adhesive tape, scrubbing with Skin-Pure jelly, and cleaning with benzine) were studied in 21 volunteers to determine whether the pretreatments could shorten the application period of transdermal 3% GA MHPh 2Na–10% lidocaine gel. Before application of the gel, each subject received skin pretreatment on the volar surface of one forearm. Then, the lidocaine gel soaked in a round sponge was applied on both the pretreated area of the forearm and the unpretreated contrast area of the other forearm. A pain score was obtained from each subject at 30, 45, 60, and 75 min after placement of the dermal patch by noting the number of painful pinpricks of five delivered. The mean pain scores on the pretreated side were significantly lower at 30, 45, and 60 min in the stripping study group and at 45 and 60 min in the cleaning study group, compared with the corresponding scores on the unpretreated side ($P < 0.05$). Skin pretreatments, such as stripping and cleaning, are useful for shortening the onset of the dermal patch anesthesia.

(Anesth Analg 1992;75:555–7)

We have developed a transdermally applicable 10% lidocaine gel mixture with 3% glycyrrhetinic acid monohemiphthalate disodium (GA MHPh 2Na) as an absorption promoter (1). A minimal 60-min application of 3% GA MHPh 2Na–10% lidocaine gel under occlusion was required to reduce a pinprick pain score <20% (1,2). Ideal dermal patch anesthesia should be more rapid in onset. Because the stratum corneum is thought to be the main barrier to the absorption of the gel through the skin, skin pretreatments that attenuate the barrier effect could shorten the application period of the gel.

The present study describes the effects of three types of skin pretreatments on the onset of dermal patch anesthesia.

Methods

After approval from the Institutional Ethics Committee on Human Research, we studied 21 healthy adult volunteers (all male, median age 31 yr, range 22–47 yr). According to the skin pretreatment to be given, the subjects were randomly allocated to one of the following three study groups: stripping ($n = 7$), scrubbing ($n = 7$), or cleaning ($n = 7$). Predictable effects of the skin pretreatments were not told to the subjects.

Both forearms were used to evaluate the effects of the skin pretreatments. Before the transdermal application of 3% GA MHPh 2Na–10% lidocaine gel, each subject received the skin pretreatment on the volar surface approximately 10 cm below the anterior cubital fossa of the left or the right forearm. In the stripping study group, 10 pieces of adhesive tape were placed on the skin and removed successively on the same area. In the scrubbing study group, approximately 1 g of Skin-Pure jelly (Nihon Koden, Japan), which is designed for electrode site cleaning to enhance stable electrocardiographic monitoring and recording by reducing electrode-to-skin impedance, was applied to the skin, and the area was scrubbed 10 times with a dry gauze pad. Then, the skin area was wiped dry of the jelly with a soft tissue. The formula of the Skin-Pure jelly was not revealed, because it was under application for a patent. In the cleaning

PT, pretreated; unPT, unpretreated.
Results are presented as mean ± SD.
[a] Significantly lower compared with the unpretreated side ($P < 0.05$).

study group, the skin area was wiped 10 times with a gauze pad containing benzine, which is a purified distillate from petroleum consisting of hydrocarbons chiefly of the methane series and is used as a solvent for organic compounds.

Then, approximately 0.3 g of the lidocaine gel soaked in a round sponge (25 mm in diameter and 1 mm thick) was applied to both the pretreated area of one forearm and the contrast unpretreated area of the other forearm and was kept covered with adhesive plastic film (Tegaderm, 3M Corp.) for 75 min. The composition of the 3% GA MHPh 2Na–10% lidocaine gel mixture is described elsewhere (1–3).

The accelerative effect of each pretreatment on the transdermal gel absorption was evaluated by comparing the analgesic effects of the gel on the forearms with and without the pretreatments. The analgesic effect was assessed with the pinprick method at 30, 45, 60, and 75 min after placement of the dermal patch by an experienced anesthesiologist who was not involved in administering the patches nor informed about the skin treatments. The cover was temporarily lifted and the sponge pulled to one side during the assessment. The gel-treated skin area was pricked five times with a disposable 26-gauge sterile needle to determine the presence or absence of pain sensation. A pain score was obtained from each subject by noting the number of painful pinpricks of the five delivered. When a pinprick induced some pain, although attenuated, it was counted as 0.5.

Statistical analysis was performed with a Wilcoxon *t*-test for comparison between pain scores on the pretreated and the unpretreated side. Values of $P < 0.05$ were considered significant.

Results

In the stripping study group, the mean pinprick pain score at 30 min (30-min pain score) was as low as 0.8 ± 0.8 (mean ± SD) on the pretreated side. The 30-, 45-, and 60-min pain scores on the pretreated side were significantly lower than the corresponding pain scores on the unpretreated side ($P < 0.05$) (Table 1, Figure 1).

In the scrubbing study group, the 30- and 45-min pain scores on the pretreated side were lower than

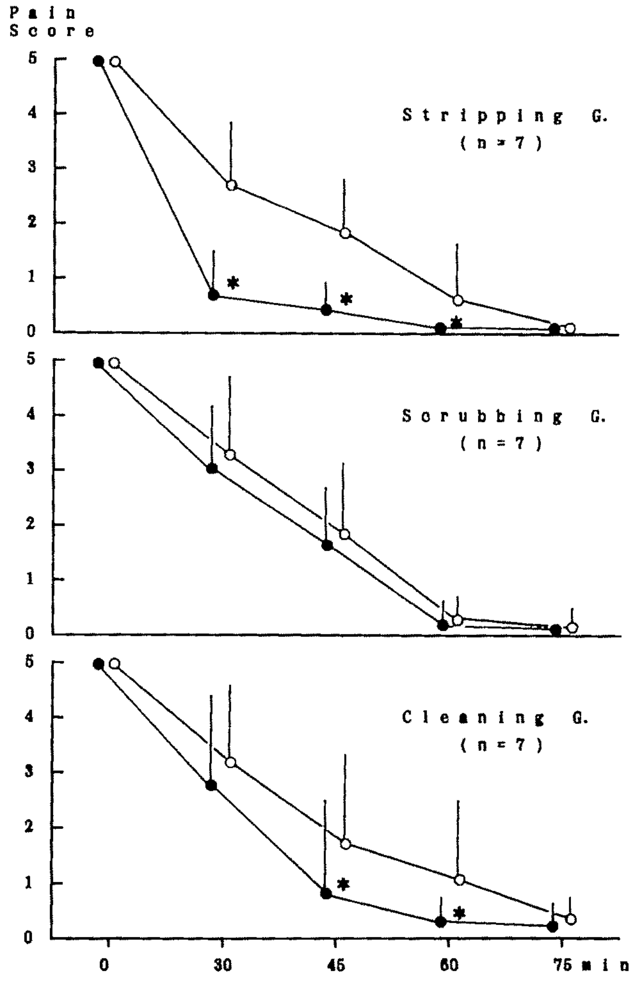

Figure 1. Comparison of pain scores between pretreated (*solid circles*) and unpretreated (*open circles*) sides after initiation of dermal patch anesthesia. G, study group. *Significantly lower compared with unpretreated side ($P < 0.05$).

the corresponding scores on the unpretreated side; however, these differences were not significant. In the cleaning study group, the 45- and 60-min pain scores on the pretreated side were significantly lower than the corresponding scores on the unpretreated side ($P < 0.05$).

Discussion

It is generally accepted that the absorption of drugs through the skin involves passive diffusion and that the main factor modulating transdermal absorption speed is penetration of the stratum corneum. Areas such as the palm and sole where the epidermal layer, especially the stratum corneum, is thick are unfavorable candidates for the transdermal absorption of drugs. On the other hand, diseased or injured skin is more permeable to transdermally applied drugs. Juhlin et al. (4) reported that after application of EMLA on the diseased skin of patients with psoriasis or atopic dermatitis, the plasma concentrations of lidocaine and prilocaine increased more rapidly and reached higher levels than were found for normal skin. Malkinson (5) reported that the skin-stripping procedure, which peels off the outer layer of the stratum corneum and reduces the barrier effect, was effective for transdermal absorption of hydrocortisone cream.

Among the pretreatments delivered in the present study, skin stripping was most effective for shortening the application time of 3% GA MHPh 2Na–10% lidocaine gel. Skin cleaning with benzine was aimed at removal of the sebum, a thin lipid layer covering the external surface of the stratum corneum, because 3% GA MHPh 2Na–10% lidocaine gel is hydrophilic. Contrary to our expectation, benzine pretreatment failed to accelerate the onset of skin analgesia in the dermal patch of 3% GA MHPh 2Na–10% lidocaine gel. Skin scrubbing with Skin-Pure jelly, which was expected to remove both the surface lipid and outer corneum layers of the epidermis, significantly shortened the application time of the lidocaine gel, as did skin stripping, although scrubbing was less effective than stripping.

In conclusion, skin pretreatments with stripping and cleaning shortened the onset of dermal patch anesthesia with 3% GA MHPh 2Na–10% lidocaine gel by approximately 30 and 15 min, respectively.

We thank Brother F. Patrick for reviewing the English manuscript.

Vomiting After Alfentanil Anesthesia: Effect of Dosing Method

Gary S. Okum, MD, Pietro Colonna-Romano, MD, and Jan C. Horrow, MD

Department of Anesthesiology, Hahnemann University, Philadelphia, Pennsylvania

This double-blind study correlated the association of nausea and vomiting after alfentanil with its method of administration (bolus dose vs continuous infusion). Of 40 women undergoing lower abdominal gynecologic or laparoscopic surgery, 20 received an intravenous alfentanil (30 μg/kg) bolus dose for induction of anesthesia, with subsequent bolus doses of 10 μg/kg every 10 min, and 20 received the same induction dose delivered over 1 min, followed by an intravenous infusion at 1.0 $\mu g \cdot kg^{-1} \cdot min^{-1}$. The infusion group experienced more frequent nausea and vomiting than the bolus dose group (50% vs 30%, respectively; $P = 0.0001$). Laparoscopic surgery affected the incidence of nausea and vomiting independently of the method of alfentanil administration (75% for laparoscopic vs 17% for incisional procedures; $P = 0.0001$). Laparoscopy and alfentanil infusion combined synergistically to worsen the incidence of nausea and vomiting. We conclude that alfentanil infusion for laparoscopic surgery entails a high risk for nausea and vomiting.

(Anesth Analg 1992;75:558–60)

Administration of alfentanil by continuous infusion, as opposed to intermittent bolus doses, permits more rapid awakening and less frequent use of naloxone (1); however, as with other opioids, nausea and vomiting may delay hospital discharge. We hypothesized that the incidence of this annoying side effect might be related to the mode of administration. To test this hypothesis, we performed a double-blind, randomized study in a group of female patients known to be at high risk for postoperative nausea and vomiting (2,3).

Methods

With the approval of our institution's Committee for Human Studies, 40 women, ASA physical status I or II undergoing laparoscopic or lower abdominal gynecologic surgery, gave written, informed consent for alternating assignment to a bolus (B) dose or infusion (I) group. No patient received premedication. Usual monitoring was used. Each patient received glycopyrrolate (0.2 mg IV), followed by vecuronium (10 μg/kg IV) before induction of anesthesia. In group B (n = 20), alfentanil (30 μg/kg) was administered as a rapid intravenous push. In group I, alfentanil (30 μg/kg) was administered as two consecutive 30 s infusions of 15 μg/kg. In each group, methohexital (1 mg/kg) was administered after the alfentanil. Vecuronium (90 μg/kg), tracheal intubation, and 65%–75% inspired N_2O followed. Ventilation was controlled to maintain end-tidal CO_2 at 28–32 mm Hg.

Patients in group B received an alfentanil (10 μg/kg IV) bolus dose every 10 min for the balance of the procedure, whereas patients in group I immediately received an alfentanil infusion at 1.0 $\mu g \cdot kg^{-1} \cdot min^{-1}$. In group I, alfentanil was discontinued 5 min before the anticipated end of the procedure, whereas in group B, no further bolus doses were administered in the last 10 min of the procedure. A peripheral nerve stimulator guided additional administration of vecuronium. An 18F gastric tube was placed orally to evacuate air and gastric contents after intubation and before emergence from anesthesia. At the conclusion of surgery, glycopyrrolate (0.4–0.6 mg) and neostigmine (2.5–3.0 mg) reversed the neuromuscular blockade. Tracheal extubation occurred once the patients were fully awake.

Recovery room nurses who did not know the method of alfentanil administration collected the following data: the number of times the patient complained of nausea or vomited and the frequency of administration of antiemetics (prochlorperazine or benzquinamide), which were given to any patient who vomited more than once or who complained of nausea after vomiting once. A "prolonged postanes-

Table 1. Incidence of Nausea With Vomiting After Alfentanil Anesthesia in 40 Women Undergoing Laparoscopic or Abdominal Gynecologic Surgery

Study group	Bolus dose	Infusion	Total
Laparoscopy	60% (6/10)	100% (6/6)	75% (12/16)
Incisional	0% (0/10)	29% (4/14)	17% (4/24)
Total	30% (6/20)	50% (10/20)	40% (16/40)

Results are presented as percent (number/total) of patients; $P < 0.0001$ laparoscopy vs incisional; $P < 0.0001$ bolus vs infusion; $P < 0.0001$ synergistic effect of infusion with laparoscopy.

Table 2. Incidence of Prolonged Postanesthesia Care Unit Stay[a] After Alfentanil Anesthesia in 40 Women

Study group	Bolus dose	Infusion	Total
Laparoscopy	10% (1/10)	50% (3/6)	25% (4/16)[b]
Incisional	0% (0/10)	0% (0/14)	0% (0/24)[b]
Total	5% (1/20)	15% (3/20)	10% (4/40)

Results are presented as percent (number/total) of patients.

[a] Prolonged stay occurred when total stay exceeded 120 min and discharge was delayed because of nausea or vomiting.

[b] $P = 0.0199$ laparoscopy vs incisional by Fisher's exact test.

thesia care unit stay" designation required delay of discharge because of nausea or vomiting and total stay >120 min.

Two-tailed unpaired Student's *t*-test compared demographic data between groups. To account for the confounding effect of surgical procedure on the incidence of nausea and vomiting, multinomial logistic regression was used to analyze the separate contributions of group and type of surgery and their interaction on the incidences of nausea and vomiting, antiemetic use, and prolonged recovery room stay (4); $P < 0.05$ denoted statistical significance.

Results

Patient groups did not differ with respect to demographic variables (age 35 ± 8 [SD] yr, weight 70 ± 14 kg). Laparoscopy accounted for 16 of the 40 procedures; the remaining 24 featured either lower abdominal or vaginal incision. As per experimental design, groups did not differ with respect to total alfentanil administered (1.15 vs 1.13 $\mu g \cdot kg^{-1} \cdot min^{-1}$ median doses). Groups also did not differ with respect to duration of anesthesia (121 ± 58 [SD] min for group I; 97 ± 43 min for group B; $P = 0.145$). However, a comparison of the total amount of alfentanil administered per kilogram body weight was indeterminant (median dose 128 μg/kg for group I vs 100 μg/kg for group B; $P = 0.055$).

Table 1 displays the incidence of nausea and vomiting according to type of surgery (laparoscopic or incisional) and group (bolus dose or infusion). Nausea and vomiting occurred with no specific temporal pattern. Some patients vomited before leaving the operating room, others several hours later. Multinomial logistic regression identified strong effects of both group and type of surgery on the incidence of nausea and vomiting: patients in the infusion group suffered a higher incidence of nausea and vomiting, as did laparoscopy patients. Infusion of alfentanil during laparoscopy combined synergistically to worsen the incidence of nausea and vomiting. Despite these significant effects, type of surgery and method of alfentanil administration did not affect the need for antiemetics. However, type of surgery did impact on the incidence of prolonged recovery room stay (Table 2). All four of the patients with prolonged stay underwent laparoscopy; three of these four received alfentanil by infusion.

Discussion

These data confirm previous studies showing an increased incidence of nausea and vomiting after laparoscopy (5,6). Causative factors may include insufflation of gas into the peritoneal cavity as well as residual effects from manipulation of the abdominal viscera (2). Nitrous oxide may cause vomiting by expanding air-filled cavities in the gastrointestinal tract and inner ear (7,8). Placement of an orogastric tube does not ensure complete evacuation of intragastric air. Does nitrous oxide exacerbate nausea and vomiting after laparoscopy? The data are conflicting. In one study (9), patients received isoflurane and nitrous oxide, enflurane and nitrous oxide, or isoflurane alone for anesthesia with respective incidences of emesis of 54%, 48%, and 52%. Yet, Felts et al. (10) found a significantly higher incidence of nausea and vomiting in patients receiving enflurane with nitrous oxide and oxygen, compared with patients receiving enflurane with air and oxygen (29.3% vs 9.3%, respectively). It is interesting to compare those emesis incidences with results in the current study of 40% overall and 75% for laparoscopy patients.

Other intravenous drugs, including methohexital and neostigmine (11), could have caused vomiting independent of the use of alfentanil. Because patients of many different surgeons participated in this study, differences in surgical technique could have contributed to the findings. These technical factors include the amount of intraperitoneal manipulation, the amount of gas used to insufflate the abdomen, dwell time of the gas, and the use of electrocautery.

This study utilized nausea with vomiting as the outcome event, rejecting nausea alone because of its insignificant impact on postanesthesia care unit stay. Vomiting without nausea that did not result from opioid administration was likewise not recorded. The current protocol also ignored any relationship between incidence of emesis and menstrual cycle timing (12).

Previous work (1) failed to show a difference in antiemetic requirement after alfentanil administered as a bolus dose versus infusion; however, that study comprised only 10 patients per group receiving a much higher dose of alfentanil (150 μg/kg). Furthermore, as the current data confirm, the use of an antiemetic does not always follow nausea and vomiting. Antiemetic choices include droperidol, prochlorperazine, benzquinamide, metoclopramide, and ephedrine (13). This protocol selected antiemetics based on their proven efficacy and minimal sedative effects.

Intermittent bolus injection results in a more variable plasma and, presumably, brain level of alfentanil. Perhaps the resulting sporadic egress of the opioid from the chemoreceptor trigger zone accounts for the lower incidence of nausea and vomiting found in group B. This intriguing possibility would require a much more sophisticated study than that undertaken here.

Could accumulation of alfentanil in patients receiving more total drug cause the increased incidence of nausea and vomiting? Although a larger study would be needed to answer this question, the authors believe that if accumulation occurs, it would exert far less effect than many other factors, such as type of surgery, choice of insufflation gas and dwell time for laparoscopies, use of electrocautery, and menstrual cycle timing.

All patients receiving alfentanil by infusion for laparoscopy suffered nausea and vomiting postoperatively, whereas no patient receiving bolus alfentanil for an incisional procedure experienced nausea or vomiting. Yet, the presence of a surgical incision increases the likelihood of postoperative discomfort and nausea (14). Opioid-induced dysphoria occurs more frequently when patients lack painful stimuli. Perhaps opioid-induced emesis behaves similarly. Opioid-induced emesis seldom occurs in the presence of opioid overdose.

Same-day discharge for laparoscopy patients mandates early ambulation. Opioids exert emetic effects in the area postrema, particularly the vestibular center. Active movement induces postoperative nausea and vomiting (15). Early ambulation before opioid effects have dissipated, even with the short-acting alfentanil, may foster motion disturbance-induced nausea and vomiting.

It is not surprising that groups did not differ in antiemetic use despite the difference in frequency of nausea and vomiting. Many patients experience nausea without vomiting or vomit once with relief of nausea. Although antiemetic prophylaxis might mitigate the effects on nausea and vomiting of alfentanil infusion during laparoscopy in women, these data do not address this issue.

Nausea with vomiting does prolong recovery room stay. One might infer from these data that nausea with vomiting is not a transient phenomenon, because it prolonged recovery room stay in a significant proportion of laparoscopy patients. We caution against this deduction, because only four patients experienced a prolonged stay.

Patients given alfentanil for outpatient laparoscopy without antiemetic prophylaxis experience a high incidence of postoperative nausea with vomiting, particularly when alfentanil is infused continuously. Although prolongation of recovery room stay may occur from administration of alfentanil by infusion for laparoscopy, confirmation requires a larger cohort. These data suggest avoidance of alfentanil infusions for outpatient laparoscopy in patients receiving methohexital and nitrous oxide.

Ondansetron in the Treatment of Postoperative Vomiting: A Randomized, Double-Blind Comparison With Droperidol and Metoclopramide

Eli Alon, MD, and Sabine Himmelseher, MD

Department of Anesthesiology, University Hospital, Zurich, Switzerland

The prophylactic antiemetic efficacy of ondansetron was evaluated in a randomized, double-blind comparison with droperidol and metoclopramide in 66 patients undergoing general anesthesia for dilatation and curettage. Ten minutes before induction of anesthesia, 22 patients received a single intravenous dose of 8 mg of ondansetron, 22 others received 1.25 mg of droperidol, and the remaining 22 received 10 mg of metoclopramide. Anesthesia was induced with 3.3–5 mg/kg of intravenous thiopental and maintained with 65% nitrous oxide in oxygen and 2%–3% enflurane. Postoperatively, the incidence of vomiting was 13% with ondansetron, 45% with droperidol, and 54% with metoclopramide ($P < 0.05$; overall χ^2 test). There was no statistically significant difference in the incidence of nausea among the groups. Postoperative sedation and well-being scores were not significantly different among the groups. We conclude that preoperative prophylactic administration of ondansetron is superior to droperidol or metoclopramide in the prevention of emetic sequelae after general anesthesia for dilatation and curettage.

(Anesth Analg 1992;75:561–5)

Postoperative nausea and vomiting occur frequently in women undergoing general anesthesia for termination of pregnancy or therapeutic abortion (1); none of the currently used prophylactic antiemetic regimens are entirely successful (2). Metoclopramide has been thought to be an effective antiemetic by some investigators (3,4); others have considered its capacity to prevent postoperative emetic sequelae as questionable (5,6). There are also contradictory reports about the antiemetic efficacy of droperidol (3,5–7), and undesirable adverse effects have been described (8). Interest has therefore been focused on new antiemetic agents such as serotonin (5-HT) antagonists (2). Ondansetron is a selective 5-HT_3 receptor antagonist (9) that has proved to be effective in the prevention of cancer chemotherapy- and radiotherapy-induced emesis (10–12). Ondansetron has also appeared to be superior to metoclopramide in the control of cisplatin-induced emesis (13). Recently published investigations in patients undergoing general anesthesia showed its postoperative effectiveness when compared with placebo (14–16).

This study was designed to assess the efficacy and safety of ondansetron compared with metoclopramide and droperidol administered for prophylaxis of postoperative emesis in women undergoing general anesthesia for minor gynecologic surgery.

Methods

The study was reviewed and approved by our institution and conducted according to the principles of the Declaration of Helsinki. Sixty-seven ASA physical status I women, aged 15–37 yr, 7–14 wk pregnant, gave informed consent to participate in the study. They were scheduled to undergo general anesthesia for dilatation and curettage to terminate pregnancy or induce therapeutic abortion. Exclusion criteria included clinical or laboratory evidence of severe renal, hematologic, or hepatic abnormalities or history of drug abuse, previous allergic reactions to serotonin antagonists, or any antiemetic therapy within 24 h of surgery. The same standardized anesthetic technique was used in all patients. Subcutaneous midazolam (5 mg) was administered 45 min before induction of anesthesia. General anesthesia was induced with thiopental (3.3–5 mg/kg IV) and maintained in spontaneous ventilation with 2%–3% enflurane and 65% nitrous oxide in oxygen. The tracheas were not intubated, and stomachs were not suctioned. If required,

intravenous alfentanil was used in doses up to 0.5 mg. During the operation, no patient received any antiemetic.

On the preoperative evening, all nulliparous patients were given 0.2 mg of prostaglandin gel vaginally. At the end of each operation, 0.2 mg of methylergometrine and 5 IU of oxytocin were intravenously administered. An infusion of 1000 mL of lactated Ringer's solution containing 10 IU of oxytocin was then started.

Ten min before induction of anesthesia, 22 patients received an intravenous injection of 8 mg of ondansetron; 22 received 1.25 mg of droperidol; and 22 received 10 mg of metoclopramide. Injections were performed in a double-blind fashion over 15 s, according to a randomized plan by an independent nurse who did not participate in any other activity of the study. Arterial blood pressure and heart rate were then measured noninvasively every minute for a 10-min period, and the patients were observed for any adverse effect of the injected antiemetic.

Postoperatively, after arrival in the recovery room, the patients were monitored for a 3-h period. At 30-min intervals, arterial blood pressure and heart rate were recorded by an independent recovery room nurse who did not know which antiemetic a patient had received. Nausea, retching, and vomiting were recorded as separate entities and were always assessed by the same recovery room nurse. If a patient vomited or spontaneously complained of nausea or retching, this was recorded. Every 30 min, each patient was asked if she was comfortable. If she replied affirmatively, she was not questioned again for 30 more minutes. If she did not feel comfortable, she was asked whether she felt sick or had pain. Responses to these questions were recorded. Pain treatment consisted of 500 mg of paracetamol in the form of a suppository. If patients requested an additional antiemetic, a suppository of 50 mg of mezlocine was administered. Totally effective antiemetic response was defined as no vomiting and no request for additional antiemetic. Sedation and well-being were graded on a three-point scale. The degree of sedation was assessed as 1 = asleep, 2 = drowsy, 3 = awake; well-being, after asking the patient, was graded as 1 = poor, 2 = moderate, and 3 = comfortable. Any other special observations were also recorded.

Cardiovascular and demographic data, sedation, and well-being scores as well as amount of anesthetics, duration of anesthesia, and time of awakening after anesthesia were analyzed with the Kruskall-Wallis test. The incidence of nausea and vomiting was compared with the χ^2 test followed by the Irwin-Snedecor test. A P value <0.05 was considered significant. All values are reported as mean ± SD.

Table 1. Demographic and Anesthetic Data of 66 Gynecologic Patients Receiving a Prophylactic Antiemetic Agent

	Ondansetron group (n = 22)	Droperidol group (n = 22)	Metoclopramide group (n = 22)
Age (yr)	26.5 ± 4.9	24.2 ± 7.2	24.9 ± 5.3
Weight (kg)	60.9 ± 10.3	57.6 ± 8.7	60.8 ± 10.0
Height (cm)	163 ± 7.1	160 ± 9.8	163 ± 6.2
Gestational age (wk)	9.5 ± 1.3	9.7 ± 1.5	9.2 ± 1.3
Duration of anesthesia (min)	14.7 ± 4.5	14.4 ± 4.8	13.8 ± 4.6
Time of awakening (min)	7.4 ± 2.1	7.7 ± 3.0	6.6 ± 3.9

Mean ± SD.

Results

A total of 67 patients entered the study. One patient had to be excluded, because she had a blood loss of 1500 mL intraoperatively and had received a total dose of 30 IU of oxytocin and 0.6 mg of methylergometrine to contract the uterus. Demographic data and gestational age in the three groups were not significantly different (Table 1). Analysis of preoperative questioning did not show any significant differences with regard to the incidence of allergies, alcohol or drug intake, or history of nausea and vomiting. Review of anesthesia protocols did not reveal significant differences in the amount of anesthetics, duration of anesthesia, or time of awakening after anesthesia (Table 1). One patient in the ondansetron group and one in the metoclopramide group received an additional 0.25 mg of alfentanil; one patient in the droperidol group received 0.5 mg of alfentanil. No significant change in mean arterial blood pressure or heart rate was associated with the antiemetic administration preoperatively or postoperatively (Figures 1 and 2).

In the postoperative observation period, ondansetron treatment resulted in a significantly lower ($P < 0.05$) incidence of vomiting compared with the two other groups: 3 of 22 (13%) patients in the ondansetron group, 12 of 22 (54%) patients in the metoclopramide group, and 10 of 22 (45%) patients in the droperidol group vomited. One patient in the ondansetron group, two patients in the dropridol group, and four patients in the metoclopramide group experienced more than one episode of vomiting. The occurrence of nausea, which was 40% in the ondansetron group, 63% in the metoclopramide group, and 50% in the droperidol group, however, was not statistically different. Thirteen of 22 (59%)

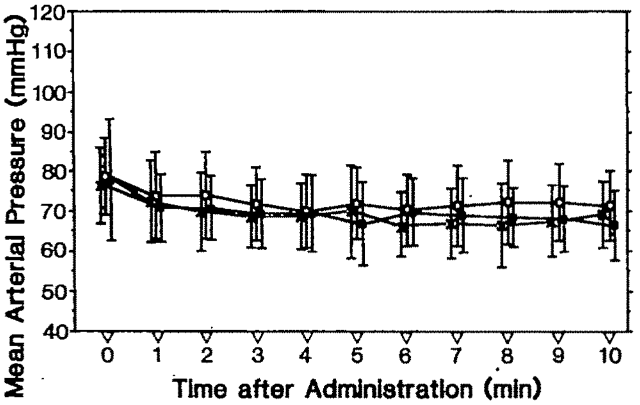

Figure 1. Mean arterial blood pressure before (0 = baseline value) and during the 10 min after injection of ondansetron (×), metoclopramide (■), and droperidol (O) before induction of anesthesia. All values are expressed as mean ± SD of 22 patients in each group. *Vertical lines* represent 1 SD.

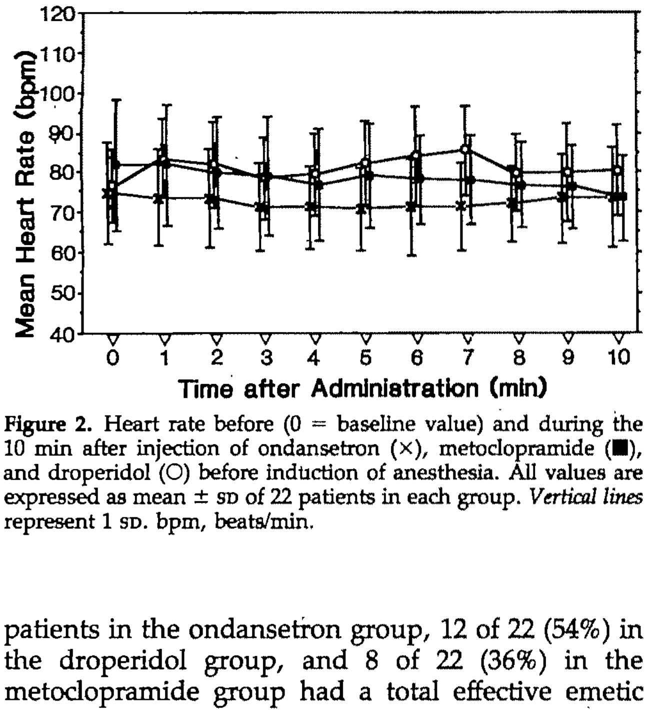

Figure 2. Heart rate before (0 = baseline value) and during the 10 min after injection of ondansetron (×), metoclopramide (■), and droperidol (O) before induction of anesthesia. All values are expressed as mean ± SD of 22 patients in each group. *Vertical lines* represent 1 SD. bpm, beats/min.

Table 2. Postanesthetic Sedation Scores of Subjects Receiving a Prophylactic Antiemetic Agent

	Time (min)					
	30	60	90	120	150	180

Sedation scores: 1 = asleep; 2 = drowsy; 3 = awake.

patients in the ondansetron group, 12 of 22 (54%) in the droperidol group, and 8 of 22 (36%) in the metoclopramide group had a total effective emetic response (statistically not different). An additional antiemetic was required by one patient subsequent to ondansetron, by three patients subsequent to metoclopramide, and by two patients subsequent to droperidol. There were no cases of protracted nausea or vomiting that needed further antiemetic therapy after the observation period.

Sedation (Table 2) and well-being scores were similar in all three groups. Apart from a short flush phenomenon and urticaria at the site of the injection in one patient immediately after administration of ondansetron, no other adverse effects were observed in this group. Subsequent to metoclopramide, one patient fell asleep, and, postoperatively, two patients experienced restlessness and shivering. After droperidol administration, three patients fell asleep, and, postoperatively, one patient complained of dizziness and five patients experienced restlessness and shivering.

Discussion

The incidence of postoperative nausea and vomiting is very high in women undergoing general anesthesia for dilatation and curettage (1,3,4). We therefore chose this patient population to evaluate the prophylactic antiemetic efficacy and safety of ondansetron compared with metoclopramide and droperidol, which are commonly used drugs. Ethical considerations dominated our decision not to use a placebo group, which is in agreement with Olver et al. (17). Although the mechanisms of postoperative emesis have not been fully elucidated, anesthesia plays a part in its etiology in addition to female gender, younger age, emotional response, and early stage of pregnancy (18–20). Thus, the use of enflurane (21) or nitrous oxide (22) may be associated with postoperative emetic sequelae. Furthermore, prostaglandins and methylergometrine are potential stimuli of nausea and vomiting (23,24). Narcotics may cause emetic symptoms, too (18); however, as the dose of the analgetic that we used was very small, only a limited statement with respect to antiemetic efficacy and opiates is possible.

In our trial of 66 patients, the incidence of postoperative vomiting was significantly less after prophylactic ondansetron (13%) compared with prophylactic metoclopramide (54%) and prophylactic droperidol (45%). This higher antiemetic efficacy of ondansetron may possibly be explained by the pharmacologic properties it is already known to have. Ondansetron as a highly selective 5-HT_3 receptor antagonist (9) blocks both peripheral and central 5-HT_3 receptors in a combined mode of action. Marty et al. (13) demonstrated the superiority of ondansetron to metoclopramide in reducing cisplatin-induced emesis in patients. Because an 8-mg intravenous dose of ondansetron administered before induction for general anesthesia with endotracheal intubation proved to be an effective antiemetic dose compared with placebo (25–27), we decided to use this amount of ondansetron for our study, too. Furthermore, Larijani et al. (15) and Bodner and White (16) showed that 8 mg of intravenous ondansetron administered during recovery from general anesthesia with intubation significantly lowered emetic episodes; Leeser and Lip (14) demonstrated that two 16-mg doses of oral ondansetron, one for premedication and one postoperatively, were effective in reducing postoperative emetic sequelae. For the prevention of postoperative nausea and vomiting, 10 mg of intravenous metoclopramide (3,5,28–30) or 1.25 mg of intravenous droperidol (5,8,29,30) has often been used, but there are contradictory findings in reports concerning the effectiveness of these two drugs. During recovery from mask anesthesia for minor gynecologic surgery, Madej and Simpson (3) reported that metoclopramide significantly reduced the incidence of nausea and vomiting, whereas Waldmann et al. (28) failed to prove that metoclopramide was effective when used in a similar anesthetic technique for therapeutic abortion. Cohen et al. (5) found that neither metoclopramide nor droperidol was capable of significantly lowering emetic symptoms after general anesthesia without tracheal intubation for therapeutic abortion. According to Melnick et al. (8), no significant differences in the incidence of postoperative nausea and vomiting were observed when droperidol was compared with placebo administered before induction of mask anesthesia for minor gynecologic surgery. On the other hand, antiemetic prophylaxis with droperidol after general anesthesia with endotracheal intubation was reported to be effective, whereas metoclopramide appeared to be ineffective (29,30). Our results show that the incidence of emesis but not of nausea was significantly lower in the ondansetron group compared with the other two groups. These findings are in agreement with Dundee and McMillan (31,32) who state that ondansetron was much more effective in preventing vomiting than in reducing nausea.

Lessin et al. (33) stated that two intravenous doses of 8 mg of ondansetron administered after the start of surgery and 8 h later did not prolong recovery time from general anesthesia compared with placebo. Kovac et al. (34) reported no significant difference, neither in recovery time nor in scores on a 10-point sedation scale, subsequent to 1, 4, or 8 mg of ondansetron administered 5 min before anesthesia compared with placebo. Using a three-point scale in our study, postoperative sedation and well-being scores were similar in the three groups. To assess postoperative sedation, Bodner and White (16) used a linear visual analogue scale with a range of 100 and described a significant difference between the ondansetron group treated with 8 mg preoperatively and the more sedated placebo group at 60 min after treatment, when 86% of the placebo group had received 20 mg of metoclopramide and 25 mg of hydroxyzine as rescue antiemetic. Furthermore, Madej and Simpson (3) did not observe significant differences with respect to postoperative sedation comparing preoperative use of 10 mg of metoclopramide with 2.5 mg of droperidol, whereas Cohen et al. (5) described a significantly longer recovery time from general anesthesia after 1.25 mg of preoperative droperidol compared with 10 mg of metoclopramide.

No adverse effects were observed in the ondansetron group in our study. This is in agreement with most authors, who describe only minor side effects in their investigations or judged them to be either unrelated or not likely to be due to ondansetron medication (14–16,25). In the literature, adverse reactions involving the nervous system after even small doses of metoclopramide have been described (3,35), and Scheller and Sears (36) report a case in which preoperative administration of the drug induced toxic neurologic reactions that were only apparent postoperatively. The use of low-dose droperidol has been described to be associated with extrapyramidal side reactions (3,37), and Melnick et al. (8) reported an incidence of postoperative anxiety or restlessness in 23% of patients, which may be related to the use of 1.25 mg of droperidol.

We conclude that 8 mg of intravenous ondansetron appears to be superior to 10 mg of metoclopramide or 1.25 mg of droperidol in preventing postoperative vomiting after general anesthesia for minor gynecologic surgery. Devoid of distressing side effects, ondansetron is a promising agent that may have an important influence on the control of perioperative emesis. Further studies comparing ondansetron with other antiemetic agents under conditions of general anesthesia for major surgical procedures and investigations to determine the optimal dose schedule for ondansetron are necessary to define its concrete position among the agents that are now commonly used.

We thank the anesthesia and recovery room nurses for their assistance.

Comparative Effects of Ketorolac, Dezocine, and Fentanyl as Adjuvants During Outpatient Anesthesia

Yifeng Ding, MD, and Paul F. White, PhD, MD, FFARACS

Department of Anesthesiology and Pain Management, University of Texas Southwestern Medical Center, Dallas, Texas; and Department of Anesthesiology, Washington University School of Medicine, St. Louis, Missouri

The comparative effects of ketorolac, dezocine, and fentanyl were evaluated in 136 healthy female patients undergoing outpatient laparoscopic procedures according to a randomized, double-blind protocol. Patients received ketorolac (60 mg) or dezocine (6 mg) or fentanyl (100 μg, control group) before the start of the operation. A standardized general anesthetic technique consisting of midazolam (2 mg), fentanyl (50 μg), and propofol (2 mg/kg) for induction of anesthesia followed by propofol (120 $\mu g \cdot kg^{-1} \cdot min^{-1}$), vecuronium (1–2 mg), and 67% nitrous oxide in oxygen for maintenance of anesthesia, was used. In the postanesthesia care unit, 61% of patients in the fentanyl group received analgesic drugs for persistent pain, compared with 34% and 25% in the ketorolac and dezocine groups, respectively. Similarly, less postoperative fentanyl (mean ± SD) was required in the ketorolac (22 ± 33 μg) and dezocine (18 ± 35 μg) groups, compared with the fentanyl (58 ± 71 μg) group. However, 52% of the patients receiving dezocine required antinausea therapy in the postanesthesia care unit, compared with 20% and 18% in the fentanyl and ketorolac groups, respectively. Finally, recovery times were significantly shorter in the ketorolac (vs dezocine) group. Although both ketorolac and dezocine were effective alternatives to fentanyl when administered during outpatient laparoscopy, dezocine was associated with an increased incidence of postoperative nausea and a delayed discharge time compared with ketorolac.

(Anesth Analg 1992;75:566–71)

Potent, rapid-acting opioid analgesics (e.g., fentanyl) are widely used adjuvants during outpatient anesthesia (1). In addition to improving intraoperative conditions, these compounds provide effective pain relief on emergence from general anesthesia. Unfortunately, opioids can increase the incidence of postoperative nausea and vomiting in the outpatient setting (2). These adverse effects have stimulated the search for alternative drugs to provide analgesia during and after outpatient anesthesia.

Ketorolac (Toradol) and dezocine (Dalgan) are parenteral analgesics that have recently been approved for clinical use in the United States. Ketorolac, a nonsteroidal antiinflammatory drug that inhibits prostaglandin synthesis, is alleged to have comparable analgesic efficacy to morphine when administered for postoperative pain relief (3,4). Dezocine is a partial μ-receptor agonist that is slightly more potent than morphine when used for postoperative pain relief (5,6). Although dezocine produces opioid-related side effects, it is considered safer than pure opioid agonists because of its "ceiling effect" with respect to respiratory depression (6,7).

Given the limited data available on the perioperative use of ketorolac and dezocine (8–10), we designed a randomized, double-blind study to compare these two compounds with fentanyl, the most widely used intraoperative analgesic, when administered during ambulatory surgery. The intraoperative conditions, recovery times, and postoperative side-effect profiles were evaluated when these three analgesic compounds were administered as part of a standardized outpatient anesthetic technique.

Methods

We studied 136 healthy (ASA physical status I or II) women scheduled for elective laparoscopic procedures, according to a double-blind protocol approved by the Washington University Human Studies Committee. Written, informed consent was obtained from each patient in the preoperative holding area. Pa-

tients were randomly assigned to receive a standardized "analgesic" dose of fentanyl (control group) or ketorolac or dezocine as an adjuvant during propofol-nitrous oxide anesthesia. The study medication (fentanyl [100 μg], ketorolac [60 mg], or dezocine [6 mg]) was prepared in a 2-mL numbered (unlabeled) syringe and was administered in a standardized manner: 1 mL IV, 1–2 min before induction with propofol and 1 mL IM after tracheal intubation. The surgeon, anesthesiologist, research nurse, and patient were all unaware of the type of analgesic medication. Pregnant women, women who had long-term analgesic or psychotropic drug therapy, and women with a history of opioid abuse or sensitivity to opioid-related side effects were excluded. Also excluded were patients with clinically significant cardiovascular, pulmonary, renal, hepatic, and neurologic diseases.

All subjects fasted for a minimum of 3 h before their scheduled surgery. No preanesthetic medication was administered. After placement of an intravenous catheter in the preoperative holding area, patients were asked to complete a baseline series of 100-mm visual analogue scales (VAS) (11–13) to assess sedation (0 = completely awake to 100 = extremely sleepy), anxiety (0 = calm to 100 = extremely nervous), pain (0 = no pain to 100 = severe pain), and nausea (0 = no nausea to 100 = severe nausea).

On arrival in the operating room, routine monitoring devices were applied, including an electrocardiogram, a noninvasive automatic blood pressure cuff, a pulse oximeter, and a precordial stethoscope. Patients were given midazolam (2 mg IV), to provide sedation, anxiolysis, and amnesia (14); lidocaine (50 mg IV), to minimize pain on injection of propofol (15,16); and fentanyl (50 μg IV), to minimize the hemodynamic response to laryngoscopy and tracheal intubation. Anesthesia was induced with propofol (2 mg/kg), at a rate of 1 $mg \cdot kg^{-1} \cdot min^{-1}$, with a Bard InfusOR pump (C.B. Bard, Inc., North Reading, Mass.). When the patient became unresponsive (loss of eyelid reflex), succinylcholine (1 mg/kg IV) was administered to facilitate tracheal intubation. A supplemental bolus dose of propofol (0.3 mg/kg) was administered if the patient manifested signs of inadequate anesthesia (e.g., hypertension, tachycardia, lacrimation). For maintenance of anesthesia, propofol was infused at an initial rate of 0.12 $mg \cdot kg^{-1} \cdot min^{-1}$ with 67% nitrous oxide in oxygen.

Before skin incision, vecuronium (1–2 mg IV) was administered to provide adequate surgical relaxation. Mean arterial blood pressure (MAP), heart rate (HR), respiratory rate, and hemoglobin oxygen saturation were recorded at 3–5-min intervals. Supplemental bolus doses of fentanyl (50 μg IV) were administered if increases in HR or MAP, or both, exceeded 20% of the preinduction baseline values and did not respond to a bolus dose of propofol (0.3 mg/kg IV) and an increase in the propofol infusion rate to 0.16 $mg \cdot kg^{-1} \cdot min^{-1}$. At the end of surgery, the propofol infusion was discontinued, and residual neuromuscular blockade was reversed with neostigmine (2.5–3 mg) and glycopyrrolate (0.4–0.6 mg IV). After reversal of residual neuromuscular blockade, nitrous oxide was discontinued.

Anesthesia time was recorded as the time from the start of induction to discontinuation of nitrous oxide. Operating time was determined from surgical incision to skin closure. Emergence times were evaluated at 30–60-s intervals from discontinuation of nitrous oxide until (a) the patient spontaneously opened her eyes (time to eye opening); and (b) the patient responded to a simple verbal command to squeeze the investigator's hand (time to following commands). Other recovery endpoints included the times from discontinuation of nitrous oxide until (a) the patient could sit up in a chair (time to sitting in a chair); (b) the patient tolerated fluids (time to oral intake); (c) the patient could walk unassisted (time to ambulation); and (d) the patient was judged to be fit for discharge or "home ready" (time to discharge).

The presence of pain and nausea were assessed at 30-min intervals after arrival in the postanesthesia care unit (PACU) by a research nurse who was unaware of the experimental treatment. Symptoms persisting on two successive evaluations were treated according to a standardized protocol. The requirements for analgesic (e.g., fentanyl) and antiemetic (e.g., metoclopramide) medications in the PACU were recorded. Discharge criteria to determine home readiness included orientation to time and place; stable vital signs on sitting up; and standing, ability to void, and ambulate without assistance (17). On entering the PACU and at 30-, 60-, 90-, and 120-min intervals postoperatively, the analogue scales were repeated to assess the patients' levels of sedation, anxiety, pain, and nausea. Finally, a follow-up questionnaire and telephone interview were completed 24 h after the operation to assess postdischarge side effects and patient satisfaction.

Data are reported as mean values ± SD (in the tables) or SEM (in the figures). Perioperative MAP and HR values for the three treatment groups were compared as a function of time after induction of anesthesia with repeated measures of analysis of variance. A Bonferroni correction was made for multiple comparison. In addition, analysis of variance and Student's *t*-test were used to analyze differences in the other continuous variables among the three treatment groups. Descriptive variables were analyzed with χ^2 tests, with P values <0.05 considered statistically significant.

Table 1. Demographic and Intraoperative Data for the Three Treatment Groups

	Fentanyl (n = 44)	Ketorolac (n = 44)	Dezocine (n = 48)
Age (yr)	33 ± 8	33 ± 8	34 ± 9
Weight (kg)	69 ± 17	65 ± 14	66 ± 13
ASA physical status (I/II)	32/12	34/10	39/9
Propofol dosages (mg)	470 ± 227	456 ± 201	441 ± 170
Supplemental fentanyl (μg)	20 ± 27	26 ± 40	25 ± 35
Operating time (min)	53 ± 38	55 ± 31	56 ± 29
Anesthesia time (min)	61 ± 38	62 ± 31	65 ± 24

Mean values ± SD (or number).

Results

The three analgesic treatment groups were comparable with respect to age, weight, ASA physical status, duration of laparoscopic procedure, and duration of anesthesia (Table 1). The propofol doses required for loss of consciousness (i.e., failure to respond to verbal commands) in the fentanyl, ketorolac, and dezocine groups were 79 ± 22, 83 ± 25, and 85 ± 27 mg, respectively. The number of patients requiring a supplemental bolus dose of propofol during the induction period was also similar in the fentanyl, ketorolac, and dezocine groups (5, 3, and 3, respectively). There were no significant differences in the total (or maintenance) dosage of propofol among the three groups. In addition, the supplemental fentanyl requirement during the operation was similar among the three groups (Table 1).

Changes in the hemodynamic variables during induction and maintenance of propofol-nitrous oxide anesthesia are summarized in Figure 1. After induction of anesthesia, there were comparable changes in MAP and HR among the three treatment groups. Immediately after laryngoscopy and intubation, the MAP returned to the preoperative baseline values in all three groups (Figure 1). The only significant hemodynamic difference among the three groups was a higher MAP at the end of anesthesia in dezocine-treated patients, compared with the fentanyl group ($P < 0.05$).

Times to eye opening and following verbal commands were similar in all three treatment groups (Table 2). Although not significantly different among the three groups, 51% of patients in the fentanyl group were able to move themselves from the operating table onto the stretcher, compared with 37% and 42% in the ketorolac and dezocine groups, respectively. The time to sitting up in a chair was also similar in all three treatment groups; however, the times to oral intake, ambulation, and discharge were significantly longer in the dezocine-treated patients compared with the ketorolac group. No significant differences were found between the ketorolac and fentanyl groups with respect to the recovery times (Table 2).

There were also no significant differences among the three groups with regard to preoperative sedation, anxiety, pain, and nausea VAS scores (Figure 2). The highest sedation VAS scores were recorded on arrival in the PACU and did not differ significantly among the three groups during the first hour in the PACU. However, ketorolac-treated patients reported a significantly lower sedation VAS score compared with the fentanyl and dezocine groups at 60 min after arriving in the PACU (Figure 2A). At the time of discharge from the PACU, all three groups still had significantly elevated sedation VAS scores compared with their preoperative baseline values ($P < 0.05$). No significant differences in anxiety VAS scores were found among the three treatment groups at any of the study intervals (Figure 2B). Patients receiving ketorolac had consistently lower pain VAS scores than those receiving fentanyl (Figure 2C). Furthermore, pain VAS scores in the ketorolac group had returned to their baseline values at the time of discharge. With the exception of patients in the dezocine group having higher nausea VAS scores at the 120-min interval than those receiving fentanyl, there were no significant differences in nausea VAS scores among the three groups (Figure 2D). However, 52% of the dezocine patients required antiemetic therapy in the PACU (vs 20% and 18% in the fentanyl and ketorolac groups, respectively). Furthermore, nausea VAS scores in the ketorolac group had returned to the preoperative baseline value at the time of discharge ($P < 0.05$).

Postoperative side effects and the requirements for parenteral analgesics and antiemetics are summarized in Table 3. A significantly higher percent of patients in the fentanyl group complained of pain in the PACU (73%) compared with patients in the ketorolac (43%) or dezocine (40%) groups. In the PACU, less analgesic (fentanyl) medication was required in the ketorolac (22 ± 33 μg, n = 34%) and dezocine (18 ± 35 μg, n = 25%) groups than in the fentanyl group (58 ± 71 μg, n = 61%). Additionally, the incidences of postoperative nausea and vomiting were significantly higher in the dezocine group than in the fentanyl and ketorolac groups ($P < 0.05$). The 24-h postoperative patient assessment questionnaire revealed that all three analgesic drugs were equally acceptable to the patients.

Discussion

Potent, rapid, and short-acting opioid analgesics are commonly used during ambulatory surgery because they improve surgical conditions (e.g., decrease pa-

Figure 1. Table 2. Recovery Times for Three Treatment Groups

	Fentanyl	Ketorolac	Dezocine
Time to eye opening (min)	3.7 ± 2.3	3.5 ± 1.9	4.2 ± 1.9
Time to following command (min)	4.4 ± 2.4	4.6 ± 2.5	5.2 ± 2.5
Time to sitting in chair (min)	75 ± 30	69 ± 22	78 ± 30
Time to oral intake (min)	96 ± 44	77 ± 31*	90 ± 44
Time to ambulation (min)	145 ± 58	122 ± 39*	165 ± 70
Time to discharge (min)	175 ± 75	141 ± 41*	194 ± 79

Mean values ± SD.
**P* < 0.05, significantly different from the dezocine group.

tient movement), and their anesthetic-sparing effects provide for a more rapid emergence from anesthesia (1,18). Although studies in the anesthesia literature suggest that dezocine also possesses anesthetic-sparing actions (19), no such data exist for ketorolac. Our study would suggest that ketorolac (60 mg) is similar to fentanyl (100 μg) and dezocine (6 mg) during outpatient laparoscopy. In addition, the intraoperative requirements for supplemental fentanyl were also similar in all three treatment groups.

The hemodynamic changes in response to tracheal intubation and surgical stimulation were identical in the three analgesic groups. Despite fentanyl (50 μg IV) and the analgesic study medication, MAP and HR values increased significantly after tracheal intubation in all three treatment groups. As all patients received similar amounts of propofol, it was not surprising that the awakening times were equally rapid (3.5 ± 1.9 to 4.2 ± 1.9 min). However, ketorolac-treated patients were able to tolerate oral fluids and ambulate sooner than patients in the dezocine group. More important, ketorolac-treated patients also required less time to be judged fit for discharge.

In the outpatient setting, intractable nausea, retching, and vomiting are among the leading causes of unexpected hospital admissions (20). Even transient nausea and vomiting can prolong the times to discharge after short gynecologic procedures (21,22). Thus, the longer time to discharge for the dezocine group was probably related to the higher incidence of emetic sequelae in that study group. Not surprisingly, the requirement for antiemetic therapy was also higher in the dezocine group. Our data for dezocine are consistent with previously published studies involving the adjunctive use of the agonist-antagonists nalbuphine and butorphanol during outpatient anesthesia (23,24). Even though >50% of the dezocine-treated patients received antiemetic therapy

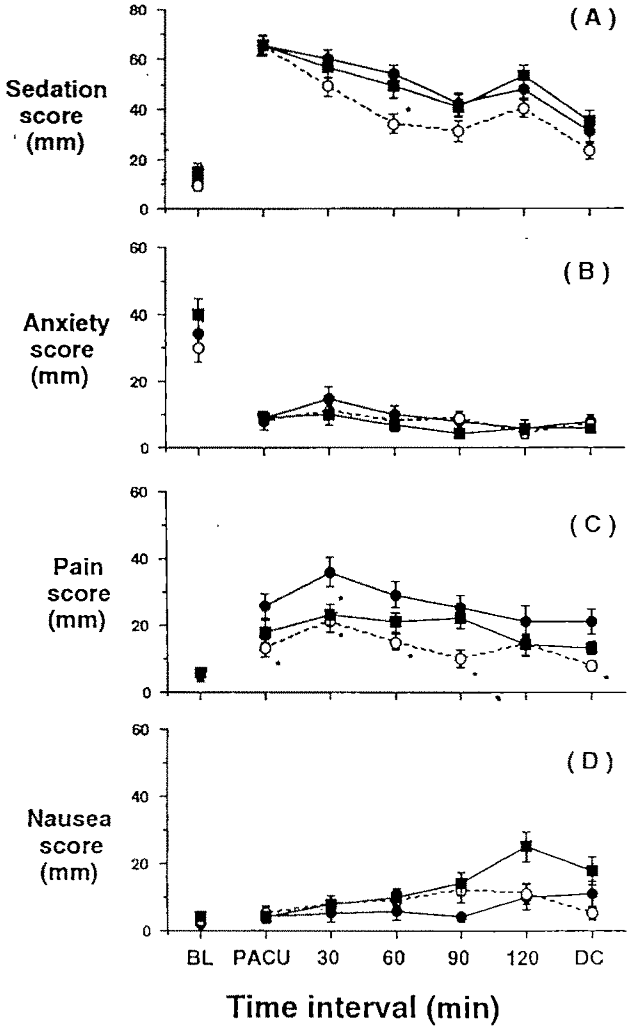

Figure 2. Visual analogue scores (VAS) in the three treatment groups: fentanyl (*solid circle*); ketorolac (*open circle*); dezocine (*square*). (A) Sedation VAS (0 = completely awake to 100 = extremely sleepy); (B) anxiety VAS (0 = calm to 100 = extremely nervous); (C) pain VAS (0 = no pain to 100 = severe pain); and (D) nausea VAS (0 = no nausea to 100 = severe nausea). Evaluation intervals included preoperative baseline (BL), on arrival in PACU (PACU), and at subsequent 30-min intervals until discharge (DC). Mean values ± SEM; *P values <0.05 considered statistically significantly different from fentanyl (control) group.

Table 3. Incidence of Pain and Other Side Effects Reported by the Nurse Observer on Direct Questioning, and Treatment for Three Treatment Groups in the Postanesthesia Care Unit

	Fentanyl	Ketorolac	Dezocine
Pain (%)	73	43[a]	40[a]
Nausea (%)	34	20	60[a]
Vomiting (%)	7	11	27[a]
Analgesic (%)	61	34[a]	25[a]
Antiemetic (%)	20	18	52[a]

[a] $P < 0.05$, significantly different from the control (fentanyl) group.

in the PACU, the nausea VAS score was still significantly higher than in the other two treatment groups 2 h after the operation.

In analyzing patient complaints of postoperative pain, both ketorolac and dezocine appeared to offer an advantage over fentanyl. The residual analgesia in the ketorolac and dezocine groups contributed to a decrease in the postoperative analgesic requirement. Compared with the fentanyl group, the patient pain and sedation VAS scores were consistently lower in the ketorolac group during the early postoperative period.

Given the improved postoperative analgesia associated with the use of ketorolac (vs fentanyl), it would seem to offer some clinical advantages over the popular rapid, short-acting opioid analgesic for outpatient laparoscopic procedures when administered during the intraoperative period. Additional studies are needed to evaluate the effectiveness of ketorolac when administered during other ambulatory surgery procedures involving both men and women.

The doses of the three analgesic compounds were chosen on the basis of open dose-ranging studies involving a similar patient population. In a preliminary study involving ketorolac (30–60 mg IM), we found that only the higher dose produced a significant anesthetic- and opioid-sparing effect (25). The dosages of the three analgesic study drugs were associated with similar intraoperative hemodynamic effects and comparable anesthetic and supplemental analgesic requirements; however, it is possible that a smaller dose of dezocine would have produced comparable postoperative analgesia with less nausea and vomiting. In addition, higher doses of fentanyl might have produced more effective postoperative analgesia without increasing side effects.

In conclusion, ketorolac (60 mg) appears to compare favorably with fentanyl (100 μg) when administered during outpatient laparoscopic procedures. In contrast to ketorolac, the use of dezocine (6 mg) resulted in an increased incidence of postoperative nausea and vomiting, contributing to a prolongation of the discharge time.

We thank Kathy Martin for her assistance in evaluating the patients during the pre- and postoperative periods and to Gerri Neumann for her assistance in typing the manuscript.

Comparison of Desflurane With Propofol in Outpatients Undergoing Peripheral Orthopedic Surgery

S. E. Rapp, MD, T. J. Conahan, MD, D. J. Pavlin, MD, W. J. Levy, MD, B. Hautman, MD, J. Lecky, MD, J. Luke, MD, and M. L. Nessly, BS

Department of Anesthesiology, University of Washington School of Medicine, Seattle, Washington, and Department of Anesthesia, University of Pennsylvania, Philadelphia, Pennsylvania

This study was undertaken to compare desflurane with propofol anesthesia in outpatients undergoing peripheral orthopedic surgery. Data were combined from two institutions participating in a multicenter study. Ninety-one patients, ASA physical status I or II, were each randomly assigned to one of four groups. After administration of fentanyl (2 μg/kg) and *d*-tubocurarine (3 mg), intravenous propofol was administered to induce anesthesia in groups I and II and desflurane in groups III and IV. Maintenance was provided by desflurane/N_2O in groups I and III, propofol/N_2O in group II, and desflurane/O_2 in group IV. Emergence and recovery variables, psychometric test results, and side effects were recorded by observers unaware of the experimental treatment. Patients in group II experienced less nausea than other groups ($P = 0.002$) despite this group having required more intraoperative fentanyl supplementation than groups III and IV ($P = 0.01$). Time to emergence, discharge, and psychometric test results were similar in all groups. Desflurane appears to be comparable with propofol as an outpatient anesthetic, facilitating rapid recovery and discharge home.

(Anesth Analg 1992;75:572–9)

The physiologic properties of desflurane suggest that it should be an effective anesthetic for use in outpatient surgery. The low arterial blood gas (0.42) and tissue gas partition coefficients predict a rapid increase and decrease of anesthetic partial pressure, facilitating both induction of and recovery from anesthesia (1,2). Minimal metabolism occurs in animals (3,4) and humans (5,6). The minimum alveolar anesthetic concentration (MAC) is 7.25% for subjects aged 18–30 yr and 6% for subjects aged 31–65 yr (7).

This randomized, prospective study was designed to evaluate the efficacy, side effects, and recovery profile of desflurane compared with propofol in outpatients undergoing peripheral orthopedic surgery. It was performed at two geographically separate institutions as part of a Food and Drug Administration (FDA) phase III testing of the clinical safety and efficacy of desflurane: University of Washington Medical Center (Center A) and University of Pennsylvania (Center B).

Methods

After approval by the human studies committees of both institutions, informed consent was obtained from 91 patients undergoing elective peripheral orthopedic surgery. The patients were ASA physical status I and II, male and female, ranging in age from 18 to 59 yr. Patients with a history of respiratory or cardiovascular disease, anemia, obesity, or chronic exposure to sedative-hypnotic, narcotic, or antidepressant medications were excluded from the study. A negative pregnancy test was required of participating women with childbearing potential.

Induction of Anesthesia

Patients at each center were randomly assigned to one of four anesthetic induction and maintenance groups (Table 1). Fentanyl (2 μg/kg) and *d*-tubocurarine (3 mg) were administered intravenously before induction of anesthesia. Anesthesia was induced with propofol (2.5 mg/kg IV) in groups I and II. An inhaled induction of anesthesia was performed in groups III (desflurane in 60% N_2O) and IV (desflurane in O_2). The concentration of desflurane delivered was initially set at 3% and thereafter increased by 3% every 4–6 breaths up to a maximum of 12%.

Table 1. Induction/Maintenance Agents in the Four Study Groups

	Group I ($n = 22$)	Group II ($n = 23$)	Group III ($n = 24$)	Group IV ($n = 22$)
Induction	Prop	Prop	Des/N_2O	Des/O_2
Maintenance	Des/N_2O	Prop/N_2O	Des/N_2O	Des/O_2

Prop, propofol; Des, desflurane.

Anesthesia was maintained by desflurane in 60% N_2O in groups I and III and by desflurane in O_2 in group IV. Group II patients received propofol (100–200 $\mu g \cdot kg^{-1} \cdot h^{-1}$), with 60% N_2O for maintenance of anesthesia.

Patients were monitored in the usual manner. A modified Datex 250 Airway Gas Analyzer (Puritan-Bennett) was used to measure end-tidal CO_2, N_2O, O_2, and desflurane. Propofol was infused by a Baxter AS206H pump. Patients receiving desflurane were anesthetized with a modified Ohmeda DM5000 (Madison, Wis.) anesthesia machine. This machine was equipped with a temperature-controlled vaporizer (23°–25°C) pressurized to approximately 1520 mm Hg to allow delivery of desflurane, which has a boiling point of 23.5°C at atmospheric pressure.

All patients were paralyzed with succinylcholine (1.5 mg/kg IV) to facilitate tracheal intubation. Ventilation was controlled to maintain end-tidal CO_2 at 38 ± 3 mm Hg (mean ± SD). Anesthetic depth was adjusted to patient need by altering the concentration of inhaled desflurane up to a maximum of 12% end-tidal concentration in groups I, III, and IV or by varying the propofol infusion rate to a maximum of 200 $\mu g \cdot kg^{-1} \cdot min^{-1}$ in group II. If the patient moved or experienced an increase in heart rate or mean arterial blood pressure >20% above awake measurements despite maximal protocol desflurane or propofol, up to three intravenous fentanyl bolus doses of 1 $\mu g/kg$ were administered per episode of light anesthesia. Muscle relaxation was provided by vecuronium (0.05–1 mg/kg), as clinically indicated (inadequate relaxation to perform surgery with no signs of inadequate anesthesia). Anesthesia was terminated on dressing placement. Arterial blood pressure and heart rate were recorded at 2-min intervals from the beginning of surgery until surgical incision, at 1-min intervals for the first 5 min of surgery, then every 15 min thereafter until dressing placement. End-tidal gas concentrations (CO_2, N_2O, desflurane), temperature, O_2 saturation, and propofol infusion rates were recorded at the same intervals as hemodynamics.

Emergence and Recovery

Variables recorded at emergence (measured in time from cessation of anesthesia) included time to opening eyes, finger squeeze, and telling name and date of birth.

Baseline psychometric testing utilizing p-deletion (8) and digit substitution tests (9) were performed in triplicate preoperatively to reduce practice effects. The best of the last two replications was used as the baseline against which subsequent performance was compared for each test. The p-deletion test consists of a sheet of 58 lines containing closely packed, single-spaced, random letters. Subjects are asked to cross out as many "p's" as they can in a 3-min period. The test provides a measure of alertness. The digit substitution test, a subtest of the Wechsler Adult Intelligence Scale (WAIS), consists of a single page with a symbol-number key at the top. The subject inserts the corresponding symbol for as many numbers as possible in a 2-min period. This test assesses the subject's ability to sustain focused attention and directed psychomotor functioning.

Recovery was evaluated by psychometric testing, pain scores, nausea and vomiting (noting the incidence, number of episodes, and severity, as well as the need for antiemetic medications), time to tolerating fluids, the sitting position, and discharge readiness. Postoperatively, psychometric testing was performed at 30-min intervals for 2 h if patients were able, regardless of whether they had received analgesics or antiemetics postoperatively. Patients unable to perform psychometric testing at any epoch received a score of zero for that time interval. Pain was assessed during the same 30-min intervals for the first 2 h after termination of the anesthetic. Pain was evaluated by the patient with verbal and visual analogue scales of 0–10 (0 = none; 10 = worst pain imaginable). Immediately postoperatively, analgesia was provided by fentanyl (25 μg) bolus doses, usually with a 100-μg maximum. Then, if necessary, patients received a dose of an oral narcotic analgesic as prescribed by their surgeon (nonstandardized by protocol). A four-point scale was used to characterize emetic symptoms: 0 = none; 1 = mild, noticeable, but not requiring treatment; 2 = moderate, requiring medication; and 3 = severe, unbearable and not responding to medication. Evaluations of nausea and vomiting occurred before administration of narcotic medications and when patients spontaneously complained of symptoms.

Choice of antiemetic therapy varied between the two institutions. Antiemetic therapy at Center A consisted of metoclopramide (10 mg IV); droperidol (0.625 mg IV, repeated once after 30 min if initially ineffective), then trimethopenzamide hydrochloride (250 mg) per rectum, or transdermal scopolamine (0.4 mg) applied to the mastoid. Center B offered atropine (0.4 mg IV), then prochlorperazine (5 mg IV).

Table 2. Demographics of 91 Patients Undergoing Peripheral Orthopedic Surgery

	Group I ($n = 22$)	Group II ($n = 23$)	Group III ($n = 24$)	Group IV ($n = 22$)	P
Gender (% female)	26.3	47.8	50.0	22.7	0.22
Age (yr)	33.5 (11.8)	34.1 (10.5)	36.8 (11.3)	31.6 (9.8)	0.46
Weight (kg)	75.7 (13.6)	74.5 (19.0)	75.0 (15.5)	81.6 (17.0)	0.44
Duration of surgery (min)	43.4 (24.8)	53.9 (45.6)	56.8 (41.0)	54.0 (24.9)	0.62
Previous surgery (%)	90.9	78.3	79.2	72.9	0.49

Mean (SD); no statistically significant differences between groups.

Statistical Analysis

Continuously distributed variables are presented as mean values (mean [SD]). One-way analysis of variance was used to compare variables measured only once. Comparisons of treatment effects of variables measured repeatedly over the postoperative period were made by significance testing of the group time interaction terms of the two-factor repeated measures analysis of variance with time as the repeated factor. Adjustment for center effects was by multivariate regression. Multiple-range testing was done by the Student-Newman-Keuls test when the analysis of variance omnibus null hypothesis was rejected. Binary coded or categoric data are presented as percentiles of the sample in the treatment group, and group differences were tested by χ^2 analysis with correction for continuity. Multiple-range testing for contingency tables was done by the critical ratio test, with one degree of freedom (10).

A two-tailed critical significance level of 0.05 was used throughout. The P values presented are nominal, with no correction for type I error due to the multiplicity of significance testing (other than that implicit in the multiple-range testing). Statistical computations were performed with SAS software (VMS release 6.06 on VAX 8600) (11).

Results

Data from the Center A ($n = 51$) and Center B ($n = 40$) were obtained using a common study protocol. These data were then combined so that the larger number of patients would contribute power to the analysis.

Demography (age, height, weight, ASA class, and history of previous surgery) was similar for all four treatment groups (Table 2). There were no statistically significant differences detected among groups I–IV or between centers.

Despite premedication with fentanyl (2 μg/kg), inhaled induction with desflurane (groups III and IV) was accompanied by signs of airway irritation and excitatory phenomena. These included coughing (36% [group III], 42% [group IV]); breathholding (26% [group III], 45% [group IV]); laryngospasm (5% [group III], 29% [group IV]); secretions (18% [group III], 25% [group IV]); and movement (5% [group III], 45% [group IV]). Treatment with assisted ventilation and positive pressure was successful in treating excitatory behavior in all but one patient who required relaxant because of hypoxemia (O_2 saturation of arterial blood [SaO_2] 65%) accompanying laryngospasm. As might be anticipated from the second gas effect, nitrous oxide shortened the time to loss of lash reflex and unconsciousness by an average of 40 s. Despite placing most intravenous cannulas in an antecubital vein to minimize the pain, 14% and 9% of patients in groups I and II, respectively, noted pain during induction of anesthesia with propofol.

Intraoperative arterial blood pressure and heart rate were stable, and mean values did not differ significantly among groups. Figures 1 and 2 show representative hemodynamic values. Extremes (minimal and maximal) of arterial blood pressure and heart rate during induction, intubation, and maintenance in each treatment group were similar, with one exception—the mean value for maximal mean arterial blood pressure during induction was significantly higher in group III (desflurane/N_2O) than in group II (propofol/propofol) (108 vs 95 mm Hg in groups III and II, respectively; $P = 0.04$). One group IV patient (desflurane/O_2 induction and maintenance) required atropine (1 mg) for transient complete heart block (heart rate 30 beats/min). Heart rate decreased just after intubation during repeated knee examinations. Heart rate increased to 120 beats/min after atropine administration. There were no additional dysrhythmias.

Mean end-tidal desflurane concentration (time-weighted average) for values recorded from onset of induction to cessation of anesthesia approximated 1 MAC in all groups receiving desflurane (Table 3). Similarly, the mean rate of propofol infusion from immediate postintubation to dressing placement was 170 $\mu g \cdot kg^{-1} \cdot min^{-1}$. More patients in group II (propofol induction and maintenance) required supplemental fentanyl than patients in groups III and IV ($P = 0.01$). The speed of emergence (Table 4) and recovery

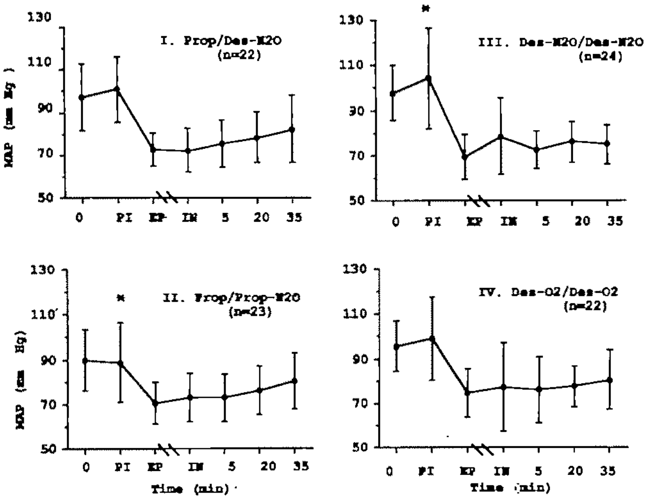

Figure 1. Representative mean arterial pressure (MAP) values (and standard deviations) showing values at 0, start of induction, immediately after intubation (PI), end of surgical preparation (EP), and surgical incision (IN), as well as at three 15-min increments during surgery for each treatment group. The *n* decreased after 35 min, secondary to surgical completion; therefore data are not presented. There was only one difference among groups as noted: *$P = 0.04$; group III > group II, immediately after intubation. Prop, propofol; Des, desflurane.

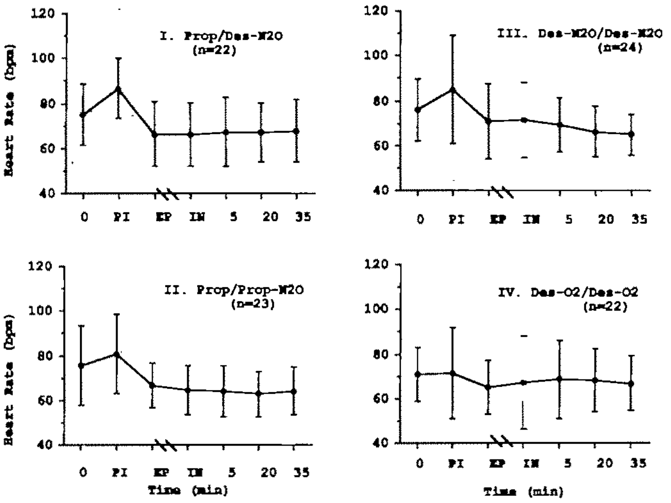

Figure 2. Representative mean heart rate (and standard deviations) from induction showing values at 0, start of induction, immediately after intubation (PI), end of surgical preparation (EP), and surgical incision (IN), as well as at three 15-min increments during surgery. The *n* decreased after 35 min, secondary to surgical completion; therefore these data are not presented. There were no detectable differences among groups. Prop, propofol; Des, desflurane; bpm, beats/min.

(Table 5) was similar in all four groups, with a few exceptions. Time to sitting was faster for patients undergoing propofol induction and maintenance (group II) compared with group IV patients ($P = 0.01$). Patients receiving propofol induction and maintenance (group II) tolerated fluids sooner ($P = 0.03$) than patients receiving a desflurane anesthetic without propofol (groups III and IV). Discharge readiness did not differ significantly among groups.

Psychometric test results were similar in all groups (Figure 3). Mean values had not returned to baseline by the time of discharge. The percent of patients attempting the tests at each time epoch are shown in Figure 4. As noted previously in Methods, those unable to attempt a test were assigned a zero score.

Nausea was experienced less often by patients who had propofol induction and maintenance compared with patients who received desflurane for maintenance (group II vs groups I, III, and IV; $P = 0.002$). Patients in group II had the least severe nausea compared with all other groups ($P = 0.003$). Group II patients also experienced fewer episodes of nausea, compared with groups III and IV ($P = 0.002$), and group I less than group III. Medical intervention for nausea or vomiting was also required more often by patients in groups I, III, and IV than in group II ($P = 0.02$).

Five patients required hospital admission: one in each of groups I and III for nausea and vomiting, one for pain in each of groups I and III, and one for urinary retention in group IV. All admitted patients were discharged in satisfactory condition the following morning. There were no other significant adverse effects identified in any patient.

Discussion

We thought it justifiable to combine data from the two institutions because of (a) use of a common protocol; (b) demographically similar groups; and (c) relatively minor differences in clinical practice between the two institutions. Analyses were done both on a center and pooled basis. Because of space limitations, we have presented only the combined, nonadjusted data. However, the results were very consistent at the two institutions, with no interactions between treatment and center effects and no differences in conclusions between centers except for emetic variables.

Induction of anesthesia proceeded as expected in all groups. Inhaled induction was rapid (142 s with N_2O, 188.4 s without) but was accompanied by significant excitatory phenomena in 20%–40% of patients. Previous investigators have reported similar excitatory phenomena during inhaled induction with desflurane (7,12–14). A smoother inhaled induction might have been attained by a more gradual increase of inspired desflurane concentration, by the addition of intravenous medications to obtund airway reflexes and irritability, or by the addition of CO_2 (15).

Pain on injection of propofol is commonplace (16,17) and is greater when infused into small distal

[e] Group II significantly different from groups III and IV; group I significantly different from group III.

veins (18). Despite the fact that we selected larger, more proximal veins for injection of propofol, we still observed pain on injection in a significant number of patients (14% and 9% in groups I and II, respectively). Possibly, the incidence could be reduced further by incorporation of lidocaine with propofol before injection (19).

Intraoperative hemodynamics were relatively stable and did not vary significantly between groups, with the exception that mean arterial pressure during

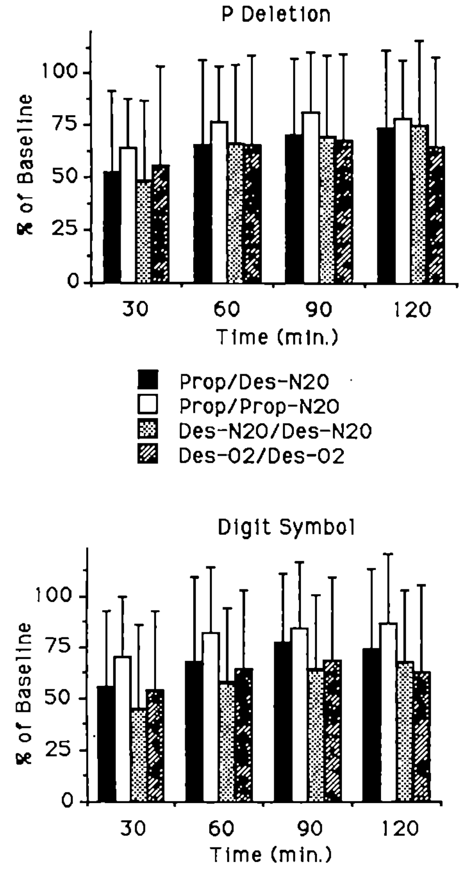

Figure 3. Percent of baseline performance on p-deletion and digit substitution tests. Groups did not differ in their performance. Prop, propofol; Des, desflurane.

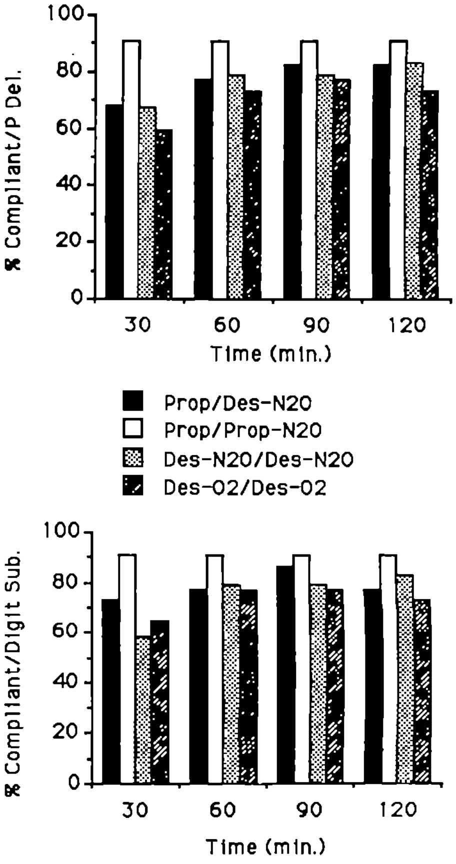

Figure 4. Percent of patients who attempted neuropsychometrics (% Compliant) at each time epoch. No statistical difference was detected among groups on either the p-deletion (P Del.) or the digit substitution (Digit Sub.) test. Prop, propofol; Des, desflurane.

induction was greater in group III than in group II (Figures 1 and 2). This transient elevation of mean arterial pressure was not judged to be clinically significant. The hemodynamic values recorded are consistent with those reported by other investigators who found that desflurane is similar to isoflurane in its hemodynamic effects (20).

Both anesthetics permitted rapid adjustment of anesthetic depth in response to surgical stimuli. The mean end-tidal desflurane concentrations were 5.4% in group I, 6.0% in group III, and 6.7% in group IV. The highest concentrations were attained in patients receiving desflurane in oxygen without nitrous oxide, as might be anticipated. End-tidal concentrations are somewhat in excess of what might be expected in groups I and III on the basis of observations of Rampil et al. (21) who reported a MAC of 4.0% (age 18–30 yr) and 2.8% (age 31–65 yr) for desflurane in surgical patients also receiving 60% N_2O. The concentrations that we report reflect adjustments made during surgery as clinically indicated in the judgment of the persons performing anesthesia, as opposed to the response to surgical incision. The use of hemodynamic variables as a means of evaluating depth may have contributed to maintaining a greater depth of anesthesia than was necessary for surgery. The use of the tourniquet in our patients may also have added to the anesthetic requirement.

It was noted that more patients receiving a propofol/N_2O anesthetic required fentanyl supplementation (Table 3) (i.e., owing to failure of maximal rate of propofol infusion to prevent movement or hemodynamic changes). This is in part related to the design of our protocol, which limited the rate of propofol infusion to 200 $\mu g \cdot kg^{-1} \cdot min^{-1}$. It may also reflect the fact that propofol is thought to be devoid of analgesic effects (22). Desflurane may provide an element of analgesia, as is the case with other halogenated anesthetics (23).

In contrast to Apfelbaum et al. (24) who reported a more rapid emergence with desflurane anesthesia compared with propofol anesthesia, we did not see a more rapid emergence in patients receiving desflurane. As an example, they recorded a time to emergence of 18 min after propofol anesthesia versus 10 min after desflurane/O_2 anesthesia (there was no desflurane/N_2O induction/maintenance group). Only emergence variables (early recovery, not later recovery variables) were noted in this study. There are several important aspects of the methodology of the two studies that might account for the differences in results. Their subjects were human volunteers who underwent 60 min of anesthesia designed to maintain hemodynamics within 20% of baseline without the use adjuvant of agents. Desflurane concentrations were not reported. In our study, the average duration of anesthesia was 43–57 min. Anesthesia was titrated to surgical stimulation as well as hemodynamic criteria. Surgical patients may require more anesthesia, which may influence speed of emergence. Fentanyl was administered preoperatively in our study and as necessary during anesthetic maintenance. Thus, the use of adjuvant medications, coupled with a desflurane concentration that may have been higher than that used in volunteers, may have contributed to longer emergence times, possibly obscuring differences between anesthetics. Normal volunteers may demonstrate less variability in response variables. This would increase power to detect a given difference as statistically significant. In any event, the differences in the speed of emergence observed by Apfelbaum et al. (24) were small and probably not of much clinical significance.

Psychometric testing also failed to demonstrate differences in the speed of recovery. This did not appear to be due to lack of sensitivity of the test, because baseline values of cognitive functioning (psychometric testing) were not achieved by any group by the time of discharge despite patients meeting the standard discharge criteria (25). It is of note in this regard that Fletcher et al. (26) recorded significant differences in the rate of return of psychomotor function when comparing patients anesthetized with desflurane versus isoflurane. However, they excluded all patients from their analysis who received analgesics or antiemetic medications during recovery from anesthesia. There are three commonly used strategies for those subjects who cannot perform neuropsychometric testing for any reason: (a) censor the noncompliant subjects; (2) assign zero scores to the noncompliant patients (as we chose to do, because bias is only present when subjects are able to do tests but refuse—this was not the case with our subjects); or, as Fletcher et al. (26) did, (c) assign the lowest score recorded for any subject in the sample at any point. Conceivably, these individuals might perform differently on psychometric testing. In our study, the decision was made in advance to evaluate all patients regardless of what additional antiemetic or analgesic drugs they received. Our study may therefore be more representative of the realities of clinical practice but less likely to demonstrate subtle differences among anesthetic techniques.

The choice of psychometric tests may also have affected the ability to detect differences among groups. The digit substitution and p-deletion tests appear to be less sensitive to changes or differences in cognitive function than choice-reaction or critical flicker fusion test, as noted by Hindmarch and Bhatti (27). It is acknowledged that the administration of antiemetics and analgesics may have affected subject performance.

The previously reported antiemetic effect of propofol (28–30) was reaffirmed in our study. Patients undergoing propofol induction and maintenance experienced significantly less nausea than patients receiving desflurane anesthetics. These patients were able to take fluids sooner despite receiving more intraoperative fentanyl. The shorter time to sitting may be attributable to the lower incidence of nausea in group II.

The use of preinduction doses of fentanyl (2 μg/kg) may have contributed to nausea. This drug was included in the protocol to blunt the hemodynamic response to endotracheal intubation. A variety of other factors may contribute to postoperative nausea. These include gender, age, perioperative narcotics, and duration of anesthesia (31). The four treatment groups in this study were of comparable gender, age, and surgical duration, and all received preoperative narcotics. Of interest, there was a slightly greater incidence of nausea reported by patients at Center A, although the relative trends among groups were similar, and statistically significant findings remained after adjusting for the effects of the two study centers in multivariate regression. The difference in the incidence of emetic symptoms between the two centers might be explained simply by random variation, by differences in the method of patient reporting, nursing practice, or intercenter difference in clinical practice. Patients at Center A were routinely offered postoperative oral fluids; at Center B, fluids were provided only on strong request. Although restriction of oral fluids per se has not been shown to decrease the incidence of nausea and vomiting (32), Watcha et al. (33) reported an inverse relationship between the "time to first oral intake" and the incidence of emesis.

In conclusion, our data suggest that desflurane is clinically comparable with propofol for outpatient orthopedic surgery insofar as safety and general efficacy are concerned. Speed of emergence, as measured by time to eye opening, following commands, and achieving orientation, did not differ among groups. Although there were some differences in achieving various milestones of recovery, time to taking fluids and ability to tolerate the sitting position were more rapid in patients undergoing a propofol anesthetic; however, fit for discharge times did not differ among groups. Both anesthetics provide for rapid emergence and acceptable recovery times.

We thank our residents and nurse anesthetists for their cooperation in the study. The assistance of our research technicians, Holly Clute, Kathy Cox, Julius Heyman, Sibyl Meyers, and Susan Taischman, who performed the patient observations and data collection, is much appreciated. We also thank Julie Baker for preparation of the manuscript.

Use of Flumazenil for Intraoperative Arousal During Spine Fusion

Ilan Eldar, MD, Noah Lieberman, MD, Rosa Shiber, MD, Jacobo Nerubay, MD, and Azriel Perel, MD

Departments of Anesthesiology and Orthopedic Surgery, Sackler School of Medicine, Tel-Aviv University, Sheba Medical Center, Tel-Hashomer, Israel

The intraoperative arousal test is used to detect potential damage to the spinal cord during spine fusion. We determined whether a continuous midazolam infusion, the effects of which are antagonized by flumazenil when the arousal test is needed, is associated with good control of the timing of arousal and with no adverse reactions. In a randomized study of 20 patients (10 in each group), we compared arousal with flumazenil during midazolam-narcotic anesthesia with an arousal test done during halothane-nitrous oxide anesthesia, both under conditions of controlled hypotension. Motor responses to verbal command were obtained 39.1 ± 36.0 s (mean ± SD) after the injection of flumazenil in eight patients. Two patients from this group awoke spontaneously 6 and 8 min after terminating the administration of nitrous oxide and midazolam but remained sedated up to the time of the test itself. In the halothane group, arousal occurred 26 ± 8.3 min after halothane administration was terminated and 10.1 ± 3.3 min after nitrous oxide was stopped. Two of the patients in this group moved, owing to early arousal 5 and 8 min before the scheduled time and needed reinstatement of anesthesia. In four patients in the halothane group, we had to wait 3–11 min after the scheduled time before satisfactory arousal was achieved. One of the patients in the halothane group showed a motor deficit of the lower limbs during the wake-up test that disappeared after decreasing the spine correction. There were no adverse reactions except for occasional shivering in the recovery period. No patient complained of any recall or unpleasant memories during the postoperative interview the following morning. We conclude that the midazolam-flumazenil technique for intraoperative arousal may be preferable to the discontinuation of halothane. The administration of flumazenil under these circumstances induces a rapid, easily controllable arousal, even under conditions of controlled hypotension.

(Anesth Analg 1992;75:580–3)

Early detection of potential damage to the spinal cord during spine fusion for correction of scoliosis is highly desirable, because a delayed diagnosis is often associated with permanent deficit (1). One of the techniques for spinal cord function monitoring is the intraoperative arousal test described by Vauzelle et al. (2). This approach gained popularity owing to its simplicity, safety, and reproducibility (1,3).

Accurate timing of the arousal test is crucial so that the patient will be awake at the right moment and any unnecessary delay in the surgical procedure will be prevented. A new anesthetic technique was described for the intraoperative arousal test (4). This method is based on a continuous midazolam infusion supplemented by narcotics, muscle relaxants, and controlled ventilation. When the arousal test was needed, the benzodiazepine antagonist flumazenil was used to antagonize the effect of midazolam with good control of the timing of arousal and no adverse reactions (4). However, this technique was not tested during the conditions of controlled hypotension, which is often used during spine surgery, nor was it compared with arousal from halothane-nitrous oxide anesthesia.

Methods

After obtaining approval by the Medical Ethics Committee, 20 ASA physical status I and II patients, aged 13–28 yr, who were scheduled for spinal fusion and instrumentation (Cotrel-Debousset procedure) for idiopathic scoliosis, were enrolled in the study after giving informed consent. Patients with psychologic problems, mental retardation, or neuromuscular deficit were excluded from the study.

Accepted for publication June 1, 1992.

After oral administration of diazepam (0.1 mg/kg) 1 h preoperatively, anesthesia was induced with 3–4 mg/kg of thiopental, preceded by fentanyl (0.1 mg IV), midazolam (2–3 mg), and pancuronium (1 mg). Paralysis was obtained by administration of succinylcholine (1 mg/kg), and the trachea was intubated. Ventilation was maintained with a mixture of 30% oxygen and 70% nitrous oxide, with an end-tidal carbon dioxide concentration of 30–38 mm Hg. A single dose of 10 mg of *d*-tubocurarine with 3 mg of pancuronium was introduced for moderate muscle relaxation at the beginning of surgery. An arterial cannula for continuous blood pressure recording, central venous line, nasogastric tube, urinary catheter, and esophageal thermometer were placed in all patients. Nitroprusside (0.25% solution) was infused in all patients to maintain mean arterial blood pressure between 50 and 60 mm Hg. Lactated Ringer's solution was administered at the rate of 6 $mL \cdot kg^{-1} \cdot h^{-1}$, and blood was transfused if the blood loss was estimated to be >10% of the estimated blood volume.

Patients were randomly assigned to one of the two study groups. In the midazolam group (*n* = 10), anesthesia was maintained with a continuous midazolam infusion at a rate of 0.2–0.3 $mg \cdot kg^{-1} \cdot h^{-1}$, supplemented with 1–2 μg/kg of fentanyl every 30 min up to 30 min before the scheduled arousal test. Intraoperative arousal in the midazolam group was produced as follows: 10 min before the scheduled arousal test, midazolam infusion and nitrous oxide were stopped, and ventilation continued with 100% oxygen. Absence of neuromuscular blockade was confirmed with a nerve stimulator. A dose of 3 μg/kg of flumazenil was injected, after which spinal cord function was assessed by the response to verbal command to move both hands and then both feet.

In the halothane group (*n* = 10), anesthesia was maintained with 0.75% halothane and 1–2 μg/kg of fentanyl every 30 min up to 30 min before the intraoperative arousal test. Intraoperative arousal was produced by stopping the administration of halothane 20 min before the scheduled arousal. Ten minutes later, when absence of neuromuscular blockade was confirmed with a nerve stimulator, nitrous oxide was stopped and ventilation was continued with 100% oxygen. Spinal cord function was assessed as mentioned previously. In both groups, anesthesia was then resumed with thiopental (3 mg/kg IV), fentanyl (0.1 mg IV), pancuronium (0.06 mg/kg), nitrous oxide, and halothane.

At the end of surgery, neuromuscular blockade was reversed with intravenous neostigmine and atropine and the tracheas were extubated. The following morning, the patients were interviewed for any recall or unpleasant memories of the procedure.

Table 1. Clinical Data for 20 Patients Undergoing Spine Fusion

	Flumazenil group (*n* = 10)	Halothane group (*n* = 10)
Age (yr)	16.6 ± 4.9	16.1 ± 3.6
Weight (kg)	46.9 ± 6.8	50.0 ± 10.7
Gender (M/F)	10:0	5:5
Length of anesthesia up to arousal (min)	181.5 ± 43.8	187.5 ± 34.6
Total length of procedure (min)	239.0 ± 42.5	246.5 ± 34.6
Temperature at arousal (°C)	35.6 ± 0.8	35.7 ± 0.8
P_{ETCO_2} pressure at arousal (mm Hg)	31.4 ± 4.7	31.9 ± 5.2
Sa_{O_2} at arousal (%)	98.0 ± 1.0	98.0 ± 1.0
Estimated blood loss (mL)	1216 ± 742	1508 ± 704

M, male; F, female; P_{ETCO_2}, end-tidal partial pressure of CO_2; Sa_{O_2}, oxyhemoglobin saturation.
Mean ± SD.

Intergroup comparisons of patient data, length of surgical procedure, temperature, end-tidal partial pressure of CO_2, oxyhemoglobin saturation, estimated blood loss, and hemodynamic data were performed by unpaired Student's *t*-test. Intragroup analysis of hemodynamic changes before and after arousal was performed by a paired *t*-test. Differences were considered significant at $P < 0.05$. Results are presented as mean ± SD.

Results

No differences were observed between the two groups with respect to age, gender, weight, length of surgical procedure, temperature, end-tidal partial pressure of CO_2, oxyhemoglobin saturation, and estimated blood loss (Table 1). Motor response to verbal command was obtained 39 ± 36 s after the injection of flumazenil in the midazolam group. Two patients in this group awoke spontaneously 6 and 8 min after termination of nitrous oxide and midazolam administration but remained sedated and motionless up to the time of the test itself.

Arousal in the halothane group occurred 26 ± 8 min after the halothane was turned off and 10 ± 3 min after administration of nitrous oxide was terminated. Two of the patients in this group showed early signs of arousal 5 and 8 min before the scheduled time. They moved and needed a short reinstatement of anesthesia with halothane to allow the surgeon to complete the instrumentation before the test. In four other patients in this group, we had to wait 3–11 minutes after the scheduled time before satisfactory arousal was achieved.

Mean arterial blood pressure increased significantly during intraoperative arousal in both groups

Table 2. Mean Arterial Pressure (MAP) and Heart Rate (HR) During the Arousal Test in the Two Study Groups

	Flumazenil group (n = 10)	Halothane group (n = 10)
MAP (mm Hg)		
Baseline[a]	55.8 ± 5.4	56.7 ± 4.3
During arousal	71.0 ± 5.3[b]	66.7 ± 5.3[b]
After arousal[c]	56.5 ± 6.6	59.5 ± 5.6
HR (beats/min)		
Baseline[a]	82 ± 12	85 ± 16
During arousal	93 ± 13	87 ± 15
After arousal[c]	82 ± 14	85 ± 16

Mean ± SD.
[a] Twenty minutes before scheduled arousal.
[b] $P < 0.01$ compared with baseline MAP.
[c] Twenty minutes after arousal.

and returned to initial baseline values after reinstatement of anesthesia (Table 2). The changes in arterial blood pressure were similar in both groups. There was no significant change in mean heart rate between prearousal and postarousal values in either of the groups (Table 2). There were no anxiety reactions, violent movements, or any other untoward incidents during the tests. One of the patients in the halothane group demonstrated good voluntary control of the hands during the wake-up test but absence of leg movement. The spine correction was decreased to the point that the motor deficit disappeared, and the patient was able to move her feet again.

In the recovery room, no neurologic deficit could be noted in any of the patients, including the patient previously mentioned. Two patients in the flumazenil group and three in the halothane group had their ventilation controlled for a short period postoperatively owing to low systemic temperature. No adverse reactions, except for occasional shivering, were recorded during the recovery period. No patient complained of any recall or unpleasant memories during the postoperative interview the following morning.

Discussion

The need for early detection of potential damage to the spinal cord during spine fusion for correction of scoliosis is unquestionable (1). There is, however, disagreement in the literature with regard to the best method for doing so, the two commonly used techniques being the intraoperative arousal test (1,2) and neurophysiologic monitoring by somatosensory evoked potentials (5).

The intraoperative arousal method is easy to use and does not require the special training and equipment that are mandatory for the neurophysiologic surveillance technique. Another problem with the latter technique is the limited choice of anesthetics, some of which distort the signal and limit its usefulness (6). The exact timing of the arousal test, however, requires experience and astute clinical judgment on the part of the anesthesiologist. The timing of arousal is especially imprecise when the anesthetic method used is based on a narcotic-muscle relaxant technique combined with inhaled anesthetics.

The recent introduction of the specific benzodiazepine antagonist flumazenil (7) has made possible the use of the intraoperative arousal technique based on the midazolam-flumazenil anesthetic method (4). The results of our study demonstrate that the benzodiazepine-antagonist technique enables the anesthesiologist to time the wake-up test accurately, even when the surgeon is not able to precisely determine the time of the test in advance. The benzodiazepine-flumazenil technique enabled us to keep the patients sedated and ready to be aroused <1 min before the test was needed. Two patients in the halothane group woke up prematurely, moved, and required the reestablishment of anesthesia for a short time. For other patients in this group, we had to wait up to 11 min after the scheduled time before satisfactory arousal was achieved.

We used a moderate dose of 3 μg/kg of flumazenil, a dose that has not been associated with any reported side effects (8,9). Indeed, none of the patients showed any abnormal response to flumazenil except for transient increases in arterial blood pressure. Patients in the halothane group showed the same significant increase in arterial blood pressure during the arousal period. We thus assume that the increase in arterial blood pressure was due to the arousal itself, not the injection of flumazenil. This assumption is supported by previous work that demonstrated that cardiovascular responses to arousal with flumazenil are minimal, even in patients with severe cardiac disease (10). The observed cardiovascular responses were not different from those seen when patients are allowed to recover spontaneously (11). Additional studies demonstrated that benzodiazepine antagonism with flumazenil does not produce acute anxiety or evidence of stress response (12). Indeed, the increases in arterial blood pressure were moderate, and the highest arterial blood pressures after arousal were still in the acceptable range.

We conclude that the midazolam-flumazenil technique for intraoperative arousal may be preferable to the discontinuation of inhaled anesthetics. The administration of flumazenil under these circumstances induces a rapid, easily controllable arousal, even under conditions of controlled hypotension.

University of California—San Diego, and VA Medical Center, San Diego, California

We studied the feasibility of recording motor evoked responses to transcranial electrical stimulation (tc^{e}-MERs) during partial neuromuscular blockade (NMB). In 11 patients, compound muscle action potentials were recorded from the tibialis anterior muscle in response to transcranial electrical stimulation during various levels of vecuronium-induced NMB. The level of NMB was assessed by accelerometry of the adductor pollicis muscle after train-of-four stimulation of the ulnar nerve. The compound muscle action potential was also recorded from the tibialis anterior muscle after direct stimulation of the peroneal nerve (M-response) as an alternative means of assessing the degree of NMB. In all patients, tc^{e}-MERs could be recorded reliably during anesthesia with N_2O and a continuous infusion of sufentanil (0.5 $\mu g \cdot kg^{-1} \cdot h^{-1}$). An intact train-of-four was present in all patients, and the amplitude of the first twitch was recorded and designated as the control value. Before administration of vecuronium, the M-response amplitude was 9.6 ± 3.6 (mean ± SD) mV, and the tc^{e}-MER amplitude was 1.21 ± 0.66 mV. Although administration of vecuronium (0.05 mg/kg) resulted in loss of the mechanical adductor pollicis response in 8 of the 11 patients, the M-response and the tc^{e}-MER remained recordable. Subsequently, during an infusion of vecuronium, adjusted to maintain one or two mechanical responses to train-of-four stimulation, the average M-response to peroneal nerve stimulation was 5.2 ± 2.5 mV (53% of the control value), and tc^{e}-MER amplitude was 0.59 ± 0.36 mV (59% of the control value). During incomplete relaxation, there was good correlation between the amplitude of the M-response and that of the tc^{e}-MER ($r = 0.75$; $P < 0.01$). The ratio of tc^{e}-MER amplitude to M-response amplitude remained constant, suggesting that it may be feasible to use the amplitude of the M-response to "calibrate" the tc^{e}-MER amplitude during vecuronium administration. The data indicate that tc^{e}-MER monitoring is feasible during clinically effective levels of NMB.

(Anesth Analg 1992;75:584–9)

Intraoperative recording of motor evoked responses to transcranial electrical or magnetic stimulation (tc^{e}-MERs) provides a method for monitoring conduction in descending motor pathways during operations in which there is a risk of spinal cord injury. The addition of tc^{e}-MERs to intraoperative somatosensory evoked response (SSER) monitoring may decrease the occurrence of false-negative results that have been reported during SSER monitoring (1,2); however, tc^{e}-MER monitoring imposes some restrictions on anesthetic technique. Our experience, and that of others, suggests that the anesthesiologist is limited to a predominantly intravenous technique, because compound muscle action potential (CMAP) responses to transcranial stimulation are abolished at very low concentrations of volatile anesthetics (3,4). In addition, it has been asserted that recording CMAPs in response to transcranial stimulation precludes administration of neuromuscular blocking drugs (5); however, various surgical procedures may be difficult to accomplish with anesthesia that omits both volatile anesthetics and muscle relaxants. Accordingly, this study was undertaken to determine whether tc^{e}-MERs could be elicited and interpreted in the presence of incomplete neuromuscular blockade.

Methods

Patient Selection

The study was approved by the local Human Subjects Committee. Written, informed consent was obtained from 11 patients scheduled to undergo lumbar laminectomy/discectomy or lumbar spinal fusion. The patients were between 18 and 50 yr of age and were of ASA physical status I or II. Patients with objective bilateral sensory or motor deficits, treated or untreated epilepsy, current or recent use of medications known to lower seizure thresholds (e.g., tricyclic antidepressants and phenothiazines), cardiac disease, and diabetes were excluded. Unilateral sensory disturbances or unilateral subjective weakness did not result in exclusion, although recordings were made from the uninvolved extremity.

No premedication was administered. Some patients received sufentanil (5–10 μg IV) preoperatively. Anesthesia was induced with etomidate (0.3–0.5 mg/kg). Succinylcholine (1–1.5 mg/kg IV) was administered to facilitate tracheal intubation. After administration of sufentanil (1–1.5 μg/kg IV), anesthesia was maintained with 66% nitrous oxide in oxygen and a continuous infusion of sufentanil (0.5 $\mu g \cdot kg^{-1} \cdot h^{-1}$ IV). When signs of light anesthesia were observed (heart rate or mean arterial pressure increase by >15% of baseline), a supplemental 10-μg bolus dose of sufentanil was administered, and the infusion rate increased by 25%.

A commercially available accelerometer designed to quantify neuromuscular blockade during clinical anesthesia (Biometer Accelograph, Biometer International, Odense, Denmark) was used to titrate the administration of vecuronium. The device quantitates the mechanical adductor pollicis (thenar) response to train-of-four (TOF) ulnar nerve stimulation at 15-s intervals by measuring the acceleration of a transducer attached to the thumb. The accelerometry technique is based on the principle that acceleration is proportional to force when mass remains constant. Because no preload is required, it is easier to set up than conventional mechanomyography. The signal from the acceleration transducer is amplified, and the "height" of the first response (T1h) is displayed as a percent of height of the first response during calibration. During neuromuscular blockade, the TOF ratio (T4/T1 × 100) is displayed when four responses to TOF stimulation are present. When less than four responses are detected, only the actual number of responses (zero, one, two, or three) is displayed. Moderate or "surgical" neuromuscular blockade is considered to be present when only one mechanical response to TOF stimulation is recordable. This corresponds to depression of the first twitch to 5%–10% of control (6).

Twenty minutes after administration of succinylcholine, the accelerometer was applied and calibrated. The patient's hand was taped to a splint to ensure unimpeded movement of the thumb. A TOF constant-current square-wave stimuli (2 Hz) of 200-μs duration was applied to the ulnar nerve every 15 s through silver/silver chloride pediatric electrocardiographic electrodes. Light abrasion of the skin was performed before electrode application to ensure that stimulus electrode impedance was <2 kΩ. Stimulus current was 60 mA, which in all patients was at least twice the current that was found to be supramaximal.

A constant voltage stimulator, specifically designed for transcranial electrical stimulation (Digitimer D180A, Digitimer Ltd., Welwyn Garden City, U.K.) was used to stimulate the motor cortex. This stimulator delivers an electrical stimulus of up to 1200 V, with a user-selectable time constant of 50 or 100 μs. Stimulus intensity is set with a rotary dial that is calibrated as percent of maximal stimulator output. Stimulation was accomplished by way of conventional silver/silver chloride electroencephalographic disk electrodes attached to the scalp with collodion and filled with electrode jelly. The anode was placed at the vertex (C_z, International 10-20 System), and the cathode was placed 7 cm anteriorly. The 100-μs time constant was used in all subjects.

The threshold stimulus intensity needed to elicit a tc^e-MER in the anesthetized patient was determined, as was the stimulus intensity at which further increases in intensity did not elicit larger responses. A stimulus intensity 20% above that found to be supramaximal was used throughout the study (500–700 V). A Cadwell Quantum 84 evoked-response analyzer was used to record CMAPs from the tibialis anterior muscle by Grass gold cup electroencephalographic electrodes applied in belly/tendon fashion. Electrode impedance was maintained at <2 kΩ. The CMAP signal was filtered between 10 and 3000 Hz, and amplifier gain was adjusted as necessary to obtain maximal vertical resolution. A time base of 100 ms was used. For each measurement, three single-sweep tc^e-MERs were acquired at 15-s intervals. The average value of these responses was used for the statistical analysis.

The tibialis anterior CMAP response to supramaximal peroneal nerve stimulation was recorded as a means of assessing the degree of neuromuscular blockade at the site of tc^e-MER recording. This response is known in the neurophysiologic literature as the muscle (M) response. To elicit the M-response, Grass needle electrodes were inserted 3 cm apart perpendicular to the peroneal nerve at the fibular head. Constant-current (60 mA) square-wave pulses of 200-μs duration were used. The recording variables and electrodes were the same as those used for the tc^e-MER recording.

After recording of baseline tc^e-MERs and M-responses (after incision, at least 30 min after induction of anesthesia and full recovery from succinylcholine), a bolus dose of 0.05 mg/kg of vecuronium was administered. Five minutes after the bolus dose of vecuronium, recordings were repeated. When neuromuscular transmission had recovered to at least one mechanical thenar response to TOF stimulation, a continuous infusion of vecuronium was started at an initial rate of 0.05 mg·kg^{-1}·h^{-1} and adjusted to maintain one to two responses to TOF stimulation. The number of responses to TOF stimulation and the percent twitch height (T1h) at the time of acquisition of each tc^{e}-MER were recorded.

Data acquired at the following intraoperative intervals were compared: *interval A*—during surgical stimulation, but before administration of vecuronium (control interval); *interval B*—5 min after administration of the loading dose of vecuronium (at which time no response to TOF stimulation was present in most subjects); and *interval C*—during the infusion of vecuronium when one or two responses to TOF stimulation were present. To minimize the influence of possible fluctuations in anesthetic depth and varying levels of surgical stimulation, for each patient the average of two to six measurements recorded during vecuronium infusion was used rather than one single measurement. All data were used in the linear regression analysis.

The tc^{e}-MER and M-response waveforms were stored on magnetic disk and analyzed off-line. For the tc^{e}-MER, onset latency and maximal peak-to-peak amplitude were determined. For the M-response, the maximal peak-to-peak amplitude of the response was determined. For each pair of waveforms, the ratio between tc^{e}-MER and M-response amplitude was calculated. The accelerometer values (twitch height of the first response [T1h] as a percent of the control response and number of responses to TOF stimulation) were recorded at the time of recording tc^{e}-MER and M-response.

Data are expressed as mean ± SD. Paired *t*-tests corrected for multiple comparisons were used to compare the data acquired at intervals B and C with the control data (interval A). A linear regression analysis of M-response versus tc^{e}-MER amplitude data pairs was performed on the pooled data from all patients.

Results

During anesthesia with sufentanil/N$_2$O, before administration of vecuronium (interval A), reproducible baseline tc^{e}-MERs and M-responses could be recorded in all patients (Table 1). The tc^{e}-MER amplitude was 1.21 ± 0.66 (mean ± SD) mV. The M-response amplitude was 9.6 ± 3.6 mV. The average ratio of tc^{e}-MER amplitude to M-response amplitude before administration of vecuronium was 0.13 ± 0.06.

Table 1. Adductor Pollicus T1 Twitch Height (T1h), Tibialis Anterior Muscle Response to Peroneal Nerve Stimulation (M-Response), and the Transcranial Electrical Motor Evoked Response (tc^{e}-MER) at Various Levels of Neuromuscular Blockade in 11 Patients Undergoing Laminectomy/Discectomy or Lumbar Spinal Fusion

	Interval A (control) (*n* = 11)	Interval B (*n* = 8)	Interval C (*n* = 11)
No. of responses to TOF stimulation (adductor pollicis accelerometry)	4	0	1–2

tc^{e}-MER/M-response ratio	0.13 ± 0.06	0.15 ± 0.10	0.13 ± 0.06

Interval A, during anesthesia and surgery before administration of vecuronium; interval B, 5 min after administration of 0.05 mg/kg of vecuronium (T1h% = 0); interval C, during infusion of vecuronium to maintain one to two responses to train-of-four (TOF) stimulation.

Results are mean ± SD.

^{a}$P < 0.05$, compared with control.

^{b}$P < 0.05$, compared with control.

Five minutes after injection of the initial bolus dose of vecuronium (0.05 mg/kg) (interval B), complete suppression of the mechanical adductor pollicis twitch was observed in 8 of the 11 patients. Figure 1 shows M-response and tc^{e}-MER waveforms from one patient before administration of vecuronium (interval A), 5 min after administration of vecuronium (interval B—no mechanical thenar response), and during infusion of vecuronium when one response to TOF stimulation was present (interval C). Despite complete suppression of mechanical twitch in most patients, both the M-response and tc^{e}-MER were recordable in all subjects (Table 1) at all times after the bolus dose of vecuronium and during the subsequent infusion (average vecuronium infusion rate 1.1 ± 0.27 μg·kg^{-1}·min^{-1}).

During the infusion of vecuronium (interval C) when one or two responses to TOF stimulation were present, T1h was 15.1% ± 7.4%. The average amplitude of the M-response to peroneal nerve stimulation was 5.2 ± 2.5 mV, and tc^{e}-MER amplitude was 0.59 ± 0.36 mV (53% and 59% of control, respectively). Regression analysis of the pooled data from all patients revealed that there was a linear relationship between M-response and tc^{e}-MER amplitudes (Figure 2). The ratio of tc^{e}-MER to M-response amplitude was unaltered at any level of neuromuscular blockade

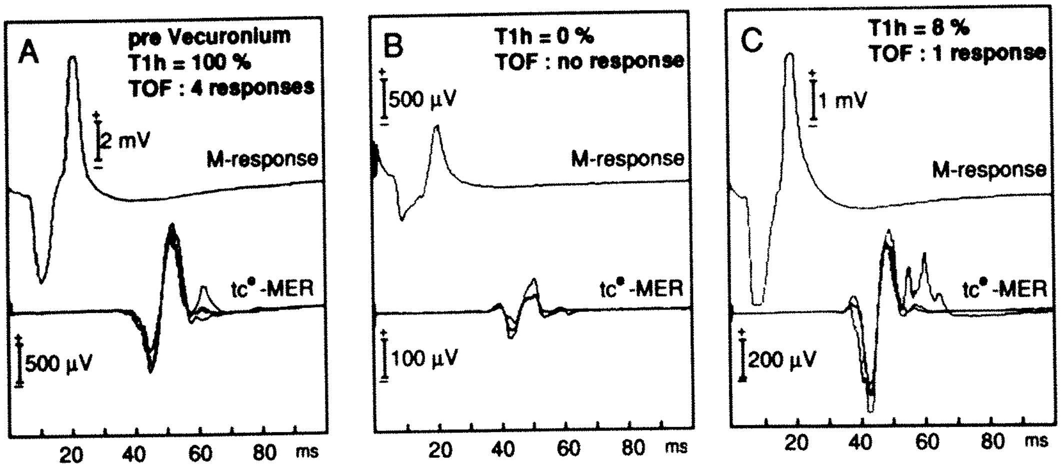

Figure 1. Tibialis anterior response to peroneal nerve stimulation (M-response) and transcranial electrical motor evoked response (tc^{e}-MER) from the same muscle before administration of vecuronium (**A**), 5 min after vecuronium (0.05 mg/kg) administration (**B**), and during a continuous infusion of vecuronium adjusted to maintain at least one response to TOF stimulation (**C**). T1h, twitch height of the adductor pollicis (as measured by accelerometry) after ulnar nerve stimulation, expressed as a percent of the control response measured during anesthesia before vecuronium administration; TOF, number of adductor pollicis responses detected after TOF stimulation.

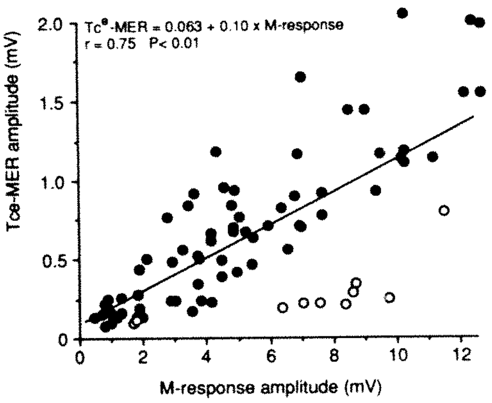

Figure 2. Relationship between tibialis anterior muscle M-response amplitude and tibialis anterior tc^{e}-MER amplitude at various levels of NMB with vecuronium (pooled data from 11 patients). The level of NMB is expressed as number of responses to TOF stimulation. The *open circles* represent data from the two patients who had a very low tc^{e}-MER/M-response amplitude ratio. Abbreviations as in Figure 1.

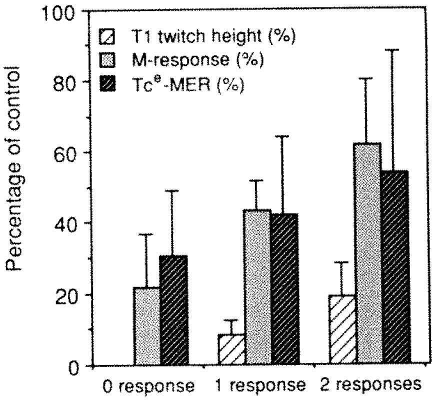

Figure 3. Relative depression of adductor pollicis T1 twitch height, tibialis anterior muscle M-response, and tc^{e}-MER during various levels of NMB, expressed as the number of twitch responses occurring after TOF stimulation of the ulnar nerve. Data are mean ± SD; $n = 6$ patients. Abbreviations as in Figure 1.

(NMB) (Table 1, Figure 3). In two patients (represented by the open circles in Figure 2), the ratio of tc^{e}-MER to M-response amplitude was obviously lower (0.025 and 0.034) than in the remainder of the group. Post-hoc examination revealed no explanation for these apparent "outliers." Preinduction tc^{e}-MERs were not recorded. Accordingly, we do not know whether these two patients, for either technical or biologic reasons, had small baseline responses or whether their tc^{e}-MERs were more depressed by the anesthetic technique than the group as a whole; however, a linear relationship between tc^{e}-MER and M-response changes was nonetheless apparent.

Average onset latency of the tc^{e}-MER before administration of vecuronium was 33.1 ± 2.57 ms. No changes in tc^{e}-MER latencies occurred at any level of neuromuscular blockade.

Discussion

The results of the present study demonstrate that tc^{e}-MERs can be readily recorded from the tibialis anterior muscle in the presence of partial neuromuscular blockade during anesthesia with sufentanil and nitrous oxide. Furthermore, they indicate that when clinical neuromuscular blockade, as judged by the TOF at the thenar eminence, has been achieved with vecuronium, the amplitude of the M-response of the tibialis anterior muscle may be reduced by as little as 55%–60% of preparalysis values. Accordingly, the results suggest that clinically substantial degrees of

NMB need not be viewed as incompatible with intraoperative tc^e-MER recording. In the clinical situation, it will probably prove most practical to select a muscle-relaxant administration technique that minimizes variation in the level of NMB (e.g., a servocontrolled infusion of relaxant); however, because the amplitude of the tc^e-MER is proportional to the amplitude of the M-response, the present results suggest that it may be feasible to use the M-response to "calibrate" the tc^e-MER to permit interpretation of the tc^e-MER amplitude when tc^e-MERs are recorded during fluctuating levels of NMB.

These observations may have considerable clinical significance, because complete omission of NMB for the purpose of tc^e-MER monitoring presents several limitations. First, as noted previously, surgical exposure may be difficult with an anesthetic regimen that uses neither volatile anesthetics nor muscle relaxants. Second, the gross movement elicited by transcranial stimulation is frequently such that the surgeon must temporarily interrupt his dissection and withdraw his instruments from the field. Third, during anesthesia with a nitrous oxide/opioid technique without NMB, there is a risk of unexpected patient movement with the attendant hazard of neurologic damage. A final disadvantage of complete absence of NMB is that spontaneous electromyographic activity may interfere with concurrent acquisition of SSERs, resulting in longer averaging times and "noisier" SSER waveforms.

Despite the admonition by some that muscle relaxants must be omitted when motor evoked responses are to be recorded (5), tc^e-MERs have been recorded during partial NMB in two previous clinical studies. Edmonds et al. (7) were able to obtain tc^e-MERs to transcranial magnetic stimulation in 9 of 11 patients during scoliosis surgery. They maintained 75%–90% NMB, as assessed by the integrated electromyographic hypothenar response to TOF ulnar nerve stimulation by giving repeated bolus doses of various NMB drugs. Calancie et al. (3) studied the effect of the introduction of isoflurane during a nitrous oxide/opioid anesthetic technique on tc^e-MER. They attempted to maintain NMB with vecuronium or atracurium at a level that retained at least two twitches to TOF stimulation. They reported that the amplitude of the M-response was typically 10%–20% of the unblocked amplitude for the first stimulus pulse. In neither study were the tc^e-MERs recorded before administration of neuromuscular blocking drugs, and as a result the relationship between level of NMB and tc^e-MER amplitude could not be completely evaluated. In ketamine-anesthetized monkeys, administration of vecuronium did not significantly decrease the opponens pollicis tc^e-MER to magnetic transcranial stimulation until M-response amplitude of the same muscle was decreased to 20% of control (8).

Our observation that the M-response persisted when the mechanical TOF response had been abolished is consistent with the findings of others. Although there is an excellent correlation between TOF ratios measured by accelerometry and mechanical force transducers (9,10), these mechanical responses have been shown previously to be more easily abolished by nondepolarizing neuromuscular blockers than the (electromyographic) M-response (11,12). Nonetheless, it is possible that a difference in sensitivity to vecuronium-induced NMB between the adductor pollicis and tibialis anterior muscle may have contributed to the relative robustness of the M-response (recorded only from the latter) during NMB. It is well known that there are major differences in sensitivity to neuromuscular blocking drugs between various muscle groups. A distal muscle such as the adductor pollicis is relatively sensitive, whereas the diaphragm is the most resistant to nondepolarizing neuromuscular blockers (13). However, Sopher et al. (14) found no difference in sensitivity to vecuronium-induced NMB, as measured by integrated electromyography between the adductor pollicis (ulnar nerve stimulation) and flexor hallucis brevis (posterior tibial nerve stimulation). We are not aware of any studies in which the tibialis anterior CMAP was compared with adductor pollicis CMAP during nondepolarizing NMB. Accordingly, we cannot completely discount the possibility that the tibialis anterior muscle is somewhat more resistant to the effects of vecuronium than the muscles of the thenar eminence.

In summary, we have demonstrated that tc^e-MERs can be recorded during anesthesia with nitrous oxide and a continuous infusion of sufentanil in the presence of clinically relevant levels of NMB, as measured by adductor pollicis accelerometry. At a T1 twitch height of 5%–15%, the reduction of tc^e-MER amplitude is 50%–60%. Provided that baseline (prerelaxant) tc^e-MER amplitude is $>150\ \mu V$, tc^e-MER monitoring should be feasible without the need for signal averaging, although simultaneous recording of the M-response will be required to permit interpretation of variations in the tc^e-MER amplitude.

We thank Steven R. Garfin, MD, Professor of Orthopedics; Steven Ozanne, MD, Division of Orthopedics and Rehabilitation; and Lawrence Marshall, MD, Professor of Neurosurgery, University of California—San Diego, for their enthusiastic support during this investigation. We are also grateful to Michael Swenson, MD, Department of Neurology, for his valuable advice, and Ron Rusk of the Anesthesia Monitoring Laboratory, University of California—San Diego Medical Center for his technical support.

Although isoflurane is a known cerebral vasodilator, the mechanism of isoflurane-induced vasodilation is not clear. The purpose of this study was to investigate the effects of 2.6% isoflurane (1.2 mM) on macroscopic calcium and potassium channel currents in voltage-clamped canine middle cerebral artery cells. Cells were dialyzed with K^+-glutamate solution and superfused with Tyrode's solution for measurement of potassium current ($n = 20$). Stepwise depolarization from a holding potential of −60 mV to beyond −30 mV elicited an outward, slowly inactivating potassium current that was reduced 50% ± 2% and 81% ± 3% (mean ± SEM) in the presence of 1 mM 4-aminopyridine and 30 mM tetraethylammonium, respectively. Calcium ionophore (A23187, 10 μM) increased the potassium current by 76% ± 3%, suggesting calcium dependency. Isoflurane reduced the amplitude of the potassium current by 35% ± 4%. Calcium current was measured in cells dialyzed with solution containing 130 mM Cs^+-glutamate and superfused with solution containing 10 mM $BaCl_2$ and 135 mM tetraethylammonium to pharmacologically isolate the calcium current ($n = 13$). Under these conditions, progressive depolarizing steps from −60 mV elicited an inward current that was maximally activated at +20 mV and essentially eliminated by 1 μM nifedipine. This current, resembling a long-lasting (L-type) Ca^{2+} channel current, was reduced 40% ± 4% by isoflurane. The results of this study suggest that isoflurane acts directly at the vascular muscle membrane to suppress transmembrane calcium and potassium currents. The decrease in calcium current would cause vasodilation; however, the concomitant decrease in potassium current may partially antagonize the depressant effect of isoflurane mediated through calcium current reduction. These effects, in interaction with other factors, may play an important role in isoflurane-induced changes of cerebral arterial tone.

(Anesth Analg 1992;75:590–6)

Volatile anesthetics alter cerebral blood flow in many animal species (1–3), as well as in humans (4,5). At the level of the cerebral vascular membrane, isoflurane may dilate cerebral arteries by altering ion channel behavior. This hypothesis has not yet been tested, and there is no study reporting the effects of any of the inhaled anesthetics on membrane currents in vascular smooth muscle.

Arterial smooth muscle tone is regulated by membrane potential that is determined primarily by voltage-dependent Ca^{2+} influx (6). Inward current through two types of Ca^{2+} channels has been identified in vascular smooth muscle cell membranes (7). The transient (T-type) Ca^{2+} current activates at more negative membrane potentials and decays rapidly, whereas the long-lasting (L-type) Ca^{2+} current activates at more positive membrane potentials and decays slowly. Calcium channels play an important role in electromechanical coupling in cerebral arteries, because the cerebral vasculature depends primarily on Ca^{2+} influx to increase cytoplasmic Ca^{2+} and to activate contractile proteins during contraction (8).

Different types of K^+ channels have also been described in vascular smooth muscle membranes (9). In the cerebral circulation, a 4-aminopyridine (4-AP)-sensitive, voltage-dependent K^+ current has been described in cat middle cerebral arterial cells (10). The common role of these K^+ channel currents is to control vascular muscle cell excitability. Activation of K^+ channels will cause membrane hyperpolarization, reducing the influx of Ca^{2+} through voltage-dependent Ca^{2+} channels and inducing vascular relaxation. The K^+ channels therefore act as an endogenous dilating mechanism to regulate vascular muscle tone (11).

The effects of isoflurane on K^+ and Ca^{2+} channel currents in vascular smooth muscle cells have not

been studied. Very little is also known about ionic currents in cerebral arterial smooth muscle. Because there are significant differences among different vascular beds with regard to the physiologic properties of K^+ and Ca^{2+} currents, the purpose of this study was to characterize K^+ and Ca^{2+} channel currents in canine middle cerebral arterial muscle cells and to use the voltage-clamp method to measure directly the effects of isoflurane on these currents. Our hypothesis was that isoflurane causes cerebral vasodilation by reducing the amplitude of the Ca^{2+} channel current or increasing that of the K^+ current, or both, at the vascular muscle membrane. However, results of this study show that isoflurane suppresses the amplitude of both K^+ and Ca^{2+} channel currents in cerebral arterial cells. Because K^+ channel block favors vascular constriction and Ca^{2+} channel suppression causes vascular dilation, the direct effects of isoflurane on the vascular muscle membrane may result in electromechanical uncoupling of vascular muscle, as previously reported with halothane in the cat middle cerebral artery (12).

Methods

After approval by the Institutional Animal Care Committee, 25 adult mongrel dogs weighing 15–25 kg were placed in a Plexiglas box and anesthetized with halothane. After attainment of surgical anesthesia, brains were removed and the middle cerebral arteries were dissected free of arachnoid and placed in a chamber containing cold Krebs' solution. Any remaining blood was cleared from the arteries, and arteries were cut into 1–2-mm rings. These were placed in an enzyme solution containing NaCl 136 mM, KCl 6.0 mM, $MgCl_2$ 1.0 mM, HEPES 10 mM, $CaCl_2$ 0.5 mM, glucose 10 mM, collagenase CLS II 500 U/mL (Worthington Co., Freehold, N.J.), dithiothreitol 4 mM (Sigma Chemical Co., St. Louis, Mo.) and papain 2 U/mL (Worthington Co.). The enzyme solution was maintained at 37°C in a water bath and stirred at 5 rpm by a microstirrer (Micro-Stir, Wheaton Instruments, Millville, N.J.). After 1–2 h, the vascular pieces were disrupted mechanically by forcing them repeatedly through a Pasteur's pipette. The cell suspension was pelleted by centrifugation at 900 rpm for 8 min. The pellet was resuspended in enzyme-free solution and placed on ice. Experiments were initiated immediately.

A drop of dispersed single arterial cells was placed in a perfusion chamber (22°C) on the stage of an inverted microscope (Olympus IMT-2, Leeds Instruments, Minneapolis, Minn.) equipped with modulation contrast. At 500× magnification, a hydraulic micromanipulator (Narishige, Tokyo, Japan) was used to position heat-polished borosilicate patch pipettes with tip resistances of 4–6 MΩ on the membranes of elongated single cerebral smooth muscle cells. High-resistance seals (3–30 GΩ) were formed, after which the pipette patch was removed by negative pressure to give electrical access to the whole cell, as previously described (13). Whole-cell currents were elicited by 200-ms depolarizing pulses generated every 5–10 s by a computerized system (Pclamp software, Axon Instruments, Burlingame, Calif.). The currents were amplified by a List EPC-7 patch-clamp amplifier (Adams & List Assoc., Great Neck, N.Y.), and the amplifier output was low-pass filtered at 500 Hz. All data were digitized (sampling rate 10,000/s) and stored on a hard disk to permit analysis at a later time. Leak and capacitative currents were subtracted from each record by linearly summating scaled currents obtained during 10-mV hyperpolarizing pulses.

The external solution used for measuring K^+ currents contained $CaCl_2$ 2.0 mM, NaCl 135 mM, KCl 4.7 mM, $MgCl_2$ 1.0 mM, glucose 10 mM, and HEPES 5 mM (pH 7.4). The pipette solution contained K^+-glutamate 130 mM, $MgCl_2$ 1.0 mM, EGTA 1.0 mM, HEPES 10 mM, and Na_2-ATP 3.0 mM (pH 7.1–7.2). The external solution used for Ca^{2+} current measurement consisted of $BaCl_2$ 10 mM, tetraethylammonium (TEA) chloride 135 mM, $MgCl_2$ 1.0 mM, glucose 10 mM, and HEPES 10 mM (pH 7.4). In the pipette solution, Cs^+ was substituted for K^+ to eliminate the K^+ current and permit isolated measurement of the Ca^{2+} current.

Repetitive current-voltage curves were obtained in the control solution to monitor time-dependent changes in K^+ current. Only cells with stable current amplitudes were exposed to isoflurane or other drugs to study their effects. After steady-state effect was established by repetitive measurements, the inflow perfusate was changed to one containing isoflurane or other drugs. Isoflurane effects were complete within 2 min. Isoflurane produced reversible decreases in K^+ currents that were verified by obtaining measurements after removal of isoflurane from the perfusate. Calcium current measurements were complicated by a time-dependent decay in the current amplitude. To circumvent this problem of Ca^{2+} current "rundown," cells for Ca^{2+} current measurement were exposed to control and isoflurane-containing solutions in random order. This protocol consisted of control measurements, followed by a second set of measurements after 3-min exposure to isoflurane. In another group of cells, measurements of Ca^{2+} current were made during isoflurane exposure, followed by control measurements after a washout period of 3 min. The solution was sampled from the perfusion chamber and analyzed by gas chromatography to verify the anesthetic concentration at the cell proximity (14). The average bath concentration of isoflurane was 1.2 ± 0.02 mM (mean ± SEM), which was calculated to correspond to 2.6 vol%. This is based on a partial pressure of 1 vol% of isoflurane, which is equivalent to a concentration of 0.46 mM in Krebs-Ringer's solution at 22°C at a pressure of 1 atm (15). Nifedipine (Sigma) was dissolved in 70% ethanol to make a 1.0-mM stock solution. The final concentration of solvent in the recording solution was 0.07%. 4-Aminopyridine (Sigma) was dissolved directly in the recording solutions. When TEA (Sigma) was used, it was substituted for Na^+ in the external solution in an equimolar concentration. The Ca^{2+} ionophore A23187 (Boehringer Mannheim GmbH, Mannheim, Germany) was dissolved in dimethyl sulfoxide at a stock concentration of 10 mM, stored at 0°C, and diluted into the extracellular solution (Tyrode's) to a final concentration of 10 μM before use. At concentrations used, solvents did not significantly alter these currents.

All currents are expressed as mean ± SEM and were analyzed by a two-way analysis of variance. If the F-test showed significance, Fisher's exact test for least significant difference was performed, with the level of significance at $P \leq 0.05$.

Results

Cells dialyzed with high-K^+ solution showed outward currents during the 200-ms depolarizing steps, changing from a holding potential of −60 mV to potentials more positive than −30 mV. This current was eliminated when Cs^+ was substituted for K^+ in the pipette solution, indicating that K^+ was probably the mandatory charge carrier for this current (16). With cell depolarization, an increasing amplitude of oscillatory current was evident to various degrees in different cells (Figure 1A). This current has been previously shown to be dependent on intracellular Ca^{2+} release (17). To better characterize the TEA-insensitive K^+ current (I_K), cells were exposed to increasing concentrations of TEA (1, 10, and 30 mM) in the external solution. Figure 1A shows the suppression of peak I_K in a single cell by increasing concentrations of TEA. Figure 1B illustrates the effect of TEA on the current-voltage relationship for K^+ channel activation ($n = 4$). Concentrations of 1, 10, and 30 mM of TEA dose-dependently reduced I_K elicited by depolarization from −60 to +60 mV to 75% ± 4%, 53% ± 3%, and 19% ± 3% of the control amplitude (622 ± 131 pA), respectively. This depression was evident at all voltages studied, and the depressant effect of TEA on I_K was completely reversible on washout.

4-Aminopyridine was a potent antagonist of the outward I_K. Figure 2A shows that concentrations of 0.1 and 1 mM 4-AP caused a dose-dependent depression of macroscopic I_K in a single cell. The effect of 4-AP on the current-voltage relationship for K^+ channel activation is shown in Figure 2B ($n = 4$). 4-Aminopyridine (0.1 and 1 mM) reduced I_K (elicited by voltage steps from −60 to +60 mV) to 75% ± 5% and 50% ± 2% of control, respectively. Therefore, 4-AP was more potent than TEA in depressing I_K.

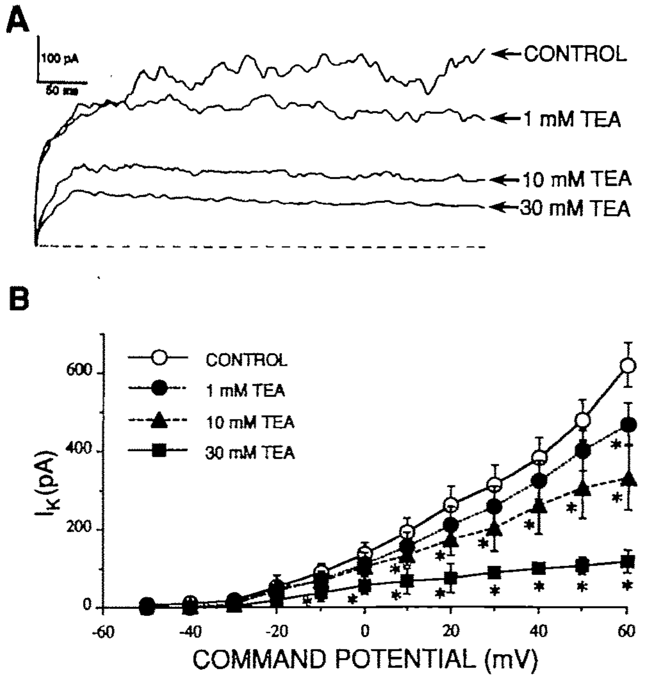

Figure 1. (A) Effects of increasing concentrations of tetraethylammonium chloride (TEA) on K^+ outward current (I_K) elicited by depolarizing pulses from a holding potential of −60 to +60 mV in one cell. (B) The current-voltage relationship for I_K activation in control solution and in the presence of TEA. TEA reduced I_K amplitude in a concentration-dependent manner throughout the entire voltage range studied. Data are mean ± SEM; $n = 4$. $*P \leq 0.05$ versus control.

In many smooth muscle cells, the major outward current in response to membrane depolarization is carried by Ca^{2+}-activated K^+ channels (18–22). To determine whether I_K in cerebral arterial cells was dependent on intracellular Ca^{2+} concentrations, I_K amplitude was measured in control (Tyrode's) solution and again after the addition of 10 μM Ca^{2+} ionophore (A23187). A23187 increases intracellular Ca^{2+} concentration by binding to the Ca^{2+} ion and conferring membrane permeability (23). Figure 3A illustrates increases in peak amplitude of I_K by 10 μM A23187 added to the external solution in one cell. A23187 increased I_K by 76% ± 3% (from control peak current 459 ± 74 pA to 808 ± 87 pA) and enhanced the entire current-voltage relationship for I_K (Figure 3B) ($n = 6$).

The effects of 2.6% isoflurane on whole-cell I_K were determined by applying a series of test pulses from a holding potential of −60 mV to more positive voltages of up to +60 mV. Figure 4A illustrates the depressant effect of isoflurane on a series of I_K recordings in one

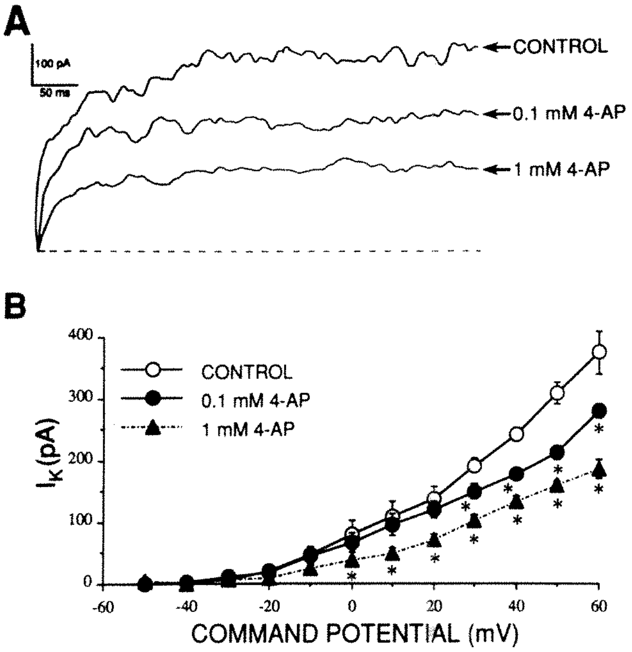

Figure 2. **(A)** Depression by 0.1 and 1 mM 4-aminopyridine (4-AP) of K^+ current (I_K) elicited by depolarization from a holding potential of −60 to +60 mV in one cell. **(B)** The control current-voltage relationship for I_K activation was depressed by 4-AP in a dose-dependent fashion at all voltages. Data are mean ± SEM; $n = 4$. $^*P \le 0.05$ versus control.

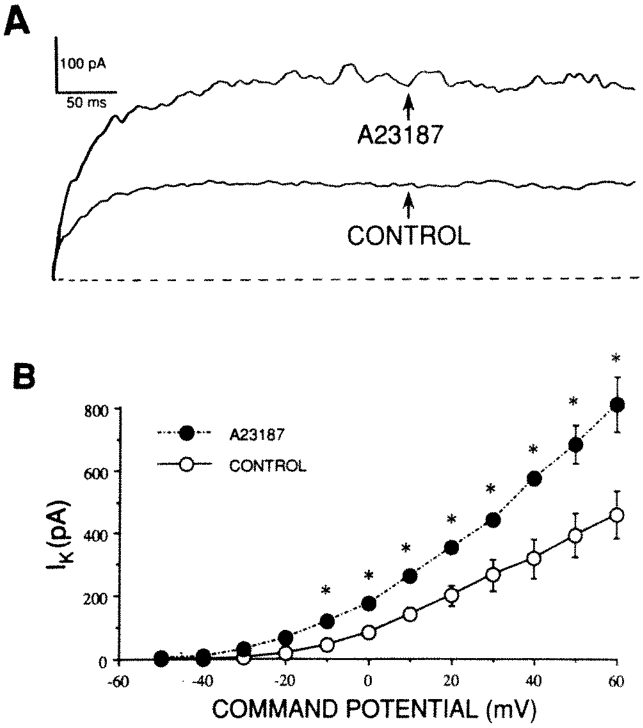

Figure 3. **(A)** Ca^{2+} dependency of K^+ outward current (I_K) was investigated by exposing canine middle cerebral arterial cells to 10 μM Ca^{2+} ionophore (A23187). The actual tracing of the effect of A23187 in the cell (which was depolarized from a holding potential of −60 to +60 mV) is shown. **(B)** The current-voltage relationship for I_K activation in control solution and in the presence of 10 μM A23187. A23187 caused significant increase in I_K, suggesting Ca^{2+} dependency. Data are mean ± SEM; $n = 6$. $^*P \le 0.05$ versus control.

cell. This effect of isoflurane on I_K was reversed completely on washout of the anesthetic agent. Peak I_K was plotted as a function of membrane potential to analyze the effect of isoflurane (Figure 4B) on the current-voltage relationship for I_K activation (expressed as percent of maximal I_K) ($n = 6$). Isoflurane decreased peak I_K amplitude throughout the voltage range studied; however, this depression was statistically significant only at voltages more positive than +40 mV.

Whole-cell Ca^{2+} current (I_{Ca}) was isolated by substituting Cs^+ for K^+ in the pipette solution and TEA for Na^+ and K^+ in the external solution, as previously detailed (24). Calcium current was generated by stepwise depolarizing pulses lasting 200 ms from a holding potential of −60 mV to a more positive command potential of up to +60 mV with barium (Ba^{2+}) as a charge carrier. In 13 cells, inward current was detected at −10 mV, and maximal activation was reached at +20 mV. Maximal I_{Ca} amplitude varied greatly between cells (range 40–230 pA; average 123 ± 29 pA).

To further characterize the channel pathway for inward current, the effects of external nifedipine (1 μM) on I_{Ca} were measured by depolarizing cells from a holding potential of −60 mV to more positive voltages of up to +60 mV. Both Ba^{2+} and nifedipine act more selectively on the L-type than the T-type Ca^{2+} channel, the former being a preferential charge carrier and the latter a specific blocker of the L-type channel (7). Nifedipine nearly abolished the I_{Ca} in a cell shown in Figure 5A. Using the same pulsing protocol, 1 μM nifedipine reduced the entire current-voltage relationship for Ca^{2+} channel activation, reducing maximal current to 17% ± 2% of the original amplitude (Figure 5B) ($n = 5$).

Administration of 2.6% isoflurane depressed I_{Ca} amplitude at all voltages studied, as shown in Figure 6A. Isoflurane decreased the entire current-voltage curve for Ca^{2+} channel activation (expressed as percent of maximal I_{Ca}). Isoflurane decreased peak I_{Ca} by 40% ± 4% from peak control current (123 ± 29 pA) (Figure 6B) ($n = 8$). This effect of isoflurane was not voltage dependent (i.e., no shift in the current-voltage relationship was observed). The isoflurane curve, when scaled up to match the control curve at maximal amplitude, was not significantly different from the control curve, supporting the conclusion that the effect of isoflurane was not voltage dependent.

Discussion

The effects of isoflurane on cerebral blood flow (CBF) have been examined in a number of studies. The

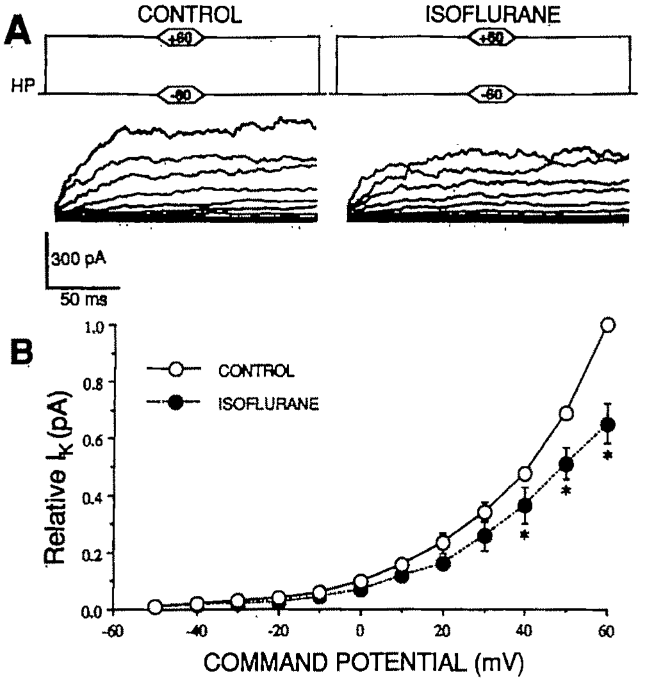

Figure 4. (A) Effect of 2.6% isoflurane on K^+ current (I_K) elicited by progressive 10-mV test pulses from −60 to +60 mV in one cell. (B) The current-voltage relationship for I_K activation in control solution and in the presence of isoflurane. Isoflurane significantly depressed I_K amplitude only at the most positive voltages studied. Data are mean ± SEM; $n = 6$. $^*P \leq 0.05$ versus control. HP, holding potential.

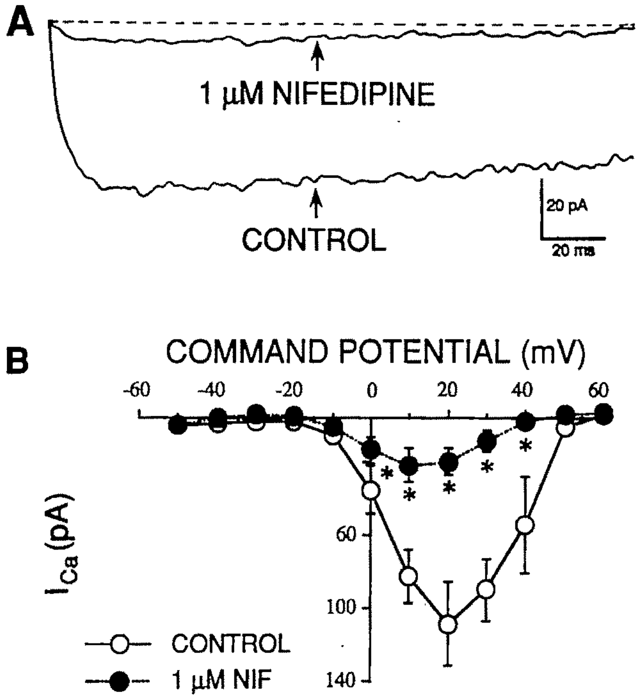

Figure 5. (A) Cells dialyzed with Cs^+-containing solution and superfused with 10 mM Ba^{2+} showed inward currents when depolarized from a holding potential of −60 mV to potentials positive to −10 mV, with maximal current activated at +20 mV. The effects of 1 μM nifedipine on peak Ca^{2+} current (I_{Ca}) elicited by depolarizing pulses from −60 to +20 mV are shown. I_{Ca} was almost completely blocked by 1 μM nifedipine. (B) The peak current-voltage relationship for I_{Ca} activation in the control solution and in the presence of 1 μM nifedipine. Data are mean ± SEM; $n = 5$. $^*P \leq 0.05$ versus control.

general conclusion is that isoflurane causes an increased ratio of oxygen supply to demand by increasing CBF caused by cerebral dilation (2,25,26) and decreasing the cerebral metabolic rate (CMR) (2). Compared with other vascular beds, large cerebral arteries play an important role in regulating total cerebral vascular resistance (27). Therefore the effects of isoflurane on the diameter of these vessels may induce significant changes in blood flow. However, it is unclear how alterations in cerebral metabolism, endothelium-derived factors, vasoactive neurotransmitters, and hormones interact with the direct action of isoflurane on the vascular muscle membrane to cause dilation. Isoflurane-induced dilation in vivo probably involves actions other than a purely direct vascular effect, because increases in CBF are accompanied by a depressed CMR (1,3). The increase in CBF concurrent with a reduced CMR suggests uncoupling between these otherwise very closely coupled variables.

In vitro, isoflurane has also been shown to be a potent dilator of cerebral arteries (28). In general, contractile mechanisms in cerebral blood vessels appear to be more dependent on extracellular Ca^{2+} influx than on intracellular stores of Ca^{2+} (8,29,30). For example, the Ca^{2+} entry blocker nimodipine is a potent dilator of cerebral vessels but has a smaller effect on peripheral vessels, further supporting the hypothesis that the entry of extracellular Ca^{2+} is critical for cerebral artery contraction (8). Thus, isoflurane-induced modulation of Ca^{2+} influx would represent a potential powerful dilator mechanism.

The dilative effects of isoflurane on cerebral blood vessels have been studied with whole-brain and regional CBF (31,32). Isoflurane was found to produce regionally selective effects on CBF in rats, having a small effect on the neocortex (31) and the greatest effect on the brainstem and cerebellum (25). The effects of isoflurane on CBF depend on the preexisting CMR (33). Isoflurane is also a potent arterial dilator in other vascular beds (34–38). The mechanism of the isoflurane-induced dilative effect is probably multifactorial because isoflurane acts at different sites and in many tissues.

The purpose of this study was to identify the cellular actions of isoflurane on K^+ and Ca^{2+} channel currents in the cerebral arterial cell membrane. We found that isoflurane reduced the amplitude of K^+ and Ca^{2+} channel currents in the vascular muscle

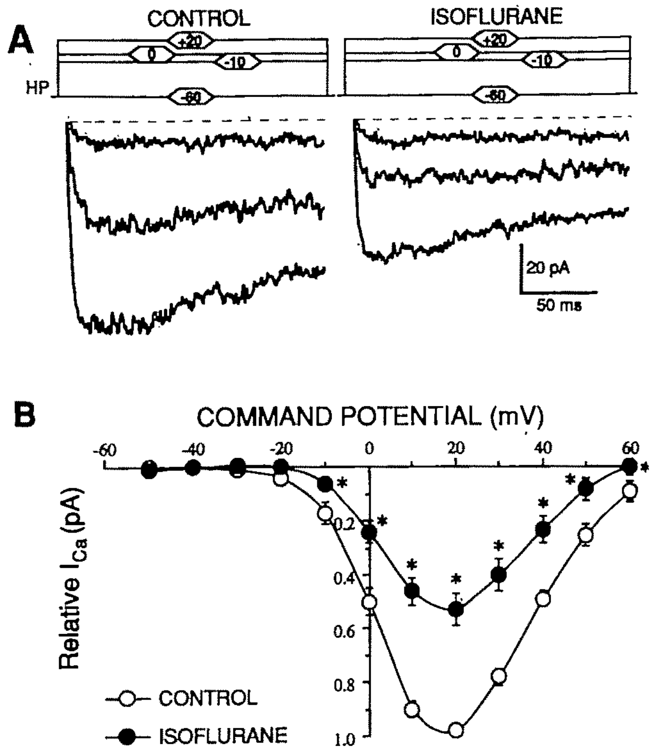

Figure 6. (A) Recordings of Ca^{2+} current (I_{Ca}) generated by progressive (10-mV increments) depolarizing pulses from −60 mV to more positive membrane potentials (up to +60 mV). Only selected episodes are shown: −60 mV (*dashed line*, holding potential, [HP]) and −10, 0, and +20 mV. Measurements during control and isoflurane were randomized to circumvent the problem of I_{Ca} rundown. (B) Peak I_{Ca} current-voltage relation obtained during control and exposure to isoflurane. Isoflurane significantly depressed I_{Ca} at all voltages studied. Data are mean ± SEM; $n = 8$. *$P \leq 0.05$ versus control.

membrane. Of these two channel types, isoflurane was a more potent blocker of the Ca^{2+} channel current at more negative membrane potentials. This was particularly evident at potentials more negative than −20 mV, which is within the physiologic range for smooth muscle cells, including cerebral arteries (39). These findings concur with previous voltage-clamp experiments showing anesthetic-induced suppression of K^+ and Ca^{2+} channel currents in cardiac Purkinje cells (14,40).

Data from this study suggest that in cerebral arterial muscle cells, isoflurane alters ionic fluxes through slowly inactivating, voltage-dependent K^+ channels and the long-lasting type Ca^{2+} channels. The macroscopic I_K measured in our study was more sensitive to 4-AP than to TEA. A similar 4-AP-sensitive, TEA-insensitive I_K has been described in pulmonary (11), coronary (22), and cat middle cerebral arteries (10). In our study, I_K was also sensitive to 10 μM A23187, suggesting Ca^{2+} dependence. These K^+ channels may modulate vasodilation and probably play an important role in regulating coronary artery tone (22). Activation of outward I_K causes cell hyperpolarization, inactivation of voltage-dependent Ca^{2+} channels, and subsequent arterial relaxation (41). This mechanism has been implicated in the prevention of vasospasm (41).

Two distinct Ca^{2+} channel types have been identified in smooth muscle tissues (7). The transient (T-type) current activates at more negative membrane potentials and decays rapidly, whereas the long-lasting (L-type) current activates at more positive membrane potentials and decays slowly. Unlike in cardiac Purkinje fibers (14) and mesenteric arteries (7), we were able only to identify the L-type Ca^{2+} channel in this preparation. The high threshold for Ca^{2+} channel current activation and effective block by nifedipine are consistent with the voltage-dependent and pharmacologic properties of the L-type Ca^{2+} channel (7,42). The isoflurane-induced block of this channel current would help to explain the direct dilative effect of isoflurane on cerebral vasculature. A reduction of Ca^{2+} influx would dilate cerebral arteries, which rely predominantly on the influx of external Ca^{2+} for the maintenance of contraction (8,30). On the other hand, the simultaneous block of K^+ channel current by isoflurane would favor membrane depolarization, because K^+ conductance is crucial for repolarization of cell membrane potential and cerebral arterial relaxation. Although this membrane depolarization may initially open voltage-dependent Ca^{2+} channels in the vascular membrane, the effective block of Ca^{2+} influx by isoflurane would probably minimize the contribution of these channels to the cytoplasmic Ca^{2+} concentration.

Taken together, the simultaneous depression of I_K and I_{Ca} by isoflurane would suggest that isoflurane could cause electromechanical uncoupling of cerebral vascular smooth muscle. The predominant action of isoflurane to reduce Ca^{2+} influx would coincide with membrane depolarization mediated by isoflurane suppression of K^+ permeability, permitting vascular relaxation coincident with membrane depolarization. This uncoupling has been demonstrated previously during exposure of cat cerebral arteries to halothane (12). The results of this study suggest that the preferential depression of I_{Ca} by isoflurane may be one mechanism to reduce cytosolic Ca^{2+} levels in arterial cells during general anesthesia and contribute to cerebral vasodilation.

A New Approach to Intravenous Regional Anesthesia

Walied Y. Abdulla, MD, ScD, and Nihal M. Fadhil, MSc

Departments of Anesthesiology, College of Medicine, University of Basrah, Basrah, Iraq, and University of Heidelberg, Heidelberg, Germany

In an attempt to reduce the dose of local anesthetic during intravenous (IV) regional anesthesia of the upper limb, we combined 100 mg of lidocaine with 0.05 mg of fentanyl and 0.5 mg of pancuronium. The study was designed in a randomized, double-blind fashion to determine the efficacy of this approach in providing analgesia and relaxation during surgery and to evaluate its safety after immediate deflation of the tourniquet following IV drug injection. Eighty unpremedicated patients, ASA physical status I or II, were assigned to the following groups: group A (n = 15) received 100 mg of lidocaine diluted in 40 mL of NaCl IV; groups B–D (n = 15 in each group) received 100 mg of lidocaine diluted in NaCl, with the addition of 0.05 mg of fentanyl (group B) or 0.5 mg of pancuronium (group C), or both (group D) to a total volume in all groups of 40 mL. Patients in groups A–D underwent elective operations on the forearm, wrist, and hand; for evaluation of safety, in 20 volunteers (group E) the tourniquet was immediately released after IV injection of the three drugs at the previously described doses. The analgesic effect was more profound in group D compared with groups A–C. In group D, 9 of 15 patients had excellent analgesia. In six patients, pain was experienced at the beginning of surgery, but 5 min thereafter patients remained pain free. In group B, analgesia was obtained successfully in only 26.6% of cases compared with group A with 13.3%. Skeletal muscle relaxation was profound in groups C and D compared with groups A and B. Signs indicating toxicity were not encountered after release of the tourniquet in these groups. In group E, the volunteers complained of minor events, such as mild dizziness and transient visual disturbances. In one case, vomiting and hypotension with a systolic arterial blood pressure of 90 mm Hg occurred 5 min after release of the tourniquet. In conclusion, this approach to IV regional anesthesia with the combination of lidocaine, fentanyl, and pancuronium offers adequate analgesia and relaxation during upper limb surgery.

(Anesth Analg 1992;75:597–601)

In intravenous (IV) regional anesthesia, with the tourniquet conventionally placed over the upper arm, a relatively large dose of local anesthetic is required to induce appropriate sensory blockade. For lidocaine, 3 mg/kg administered as a 0.5% solution ensures adequate analgesia and relaxation when used for upper limb surgery. However, toxic reactions, including convulsions, coma, cardiorespiratory depression, and even cardiac arrest have been reported (1–8). Toxicity may be due to leakage past the tourniquet after injection caused by either tourniquet failure or buildup of excessively high venous pressure distal to the tourniquet (9–11). In view of the possible central nervous system and cardiovascular toxicity, use of an alternative approach to IV regional anesthesia with fewer side effects would be desirable. Lidocaine is considered one of the least toxic local anesthetics (12) and in the usual IV dosage of 1–2 mg/kg is safe and effective for treating ventricular arrhythmias (13) or attenuating the cardiovascular response to endotracheal intubation (14). On the other hand, analgesia was insufficient when a similar dose of lidocaine administered as a 0.25% solution was used alone for IV regional anesthesia with the tourniquet placed on the upper arm (15).

Our clinical trials indicated that the addition of 0.05 mg of fentanyl and 0.5 mg of pancuronium to 100 mg of lidocaine improves the quality of analgesia and relaxation during various surgical procedures on the upper limbs. Our double-blind study was designed to establish the efficacy of this new approach to IV regional block in controlling analgesia and relaxation during surgery. Furthermore, its safety was evaluated immediately after deflation of the tourniquet following IV drug injection.

Methods

Informed consent was obtained from each patient, and the study was approved by the Hospital Human Investigation Committee. Eighty unpremedicated patients (46 male and 34 female), ASA physical status I

Accepted for publication June 1, 1992.

or II, were assigned in a randomized, double-blind fashion to the following groups: group A ($n = 15$) received 100 mg of lidocaine diluted in 40 mL of NaCl IV; groups B–D ($n = 15$ in each group) received 100 mg of lidocaine diluted in NaCl with the addition of 0.05 mg of fentanyl (group B) or 0.5 mg of pancuronium (group C), or both (group D), to a total volume in all groups of 40 mL. In group E ($n = 20$), volunteers received 100 mg of lidocaine, 0.05 mg of fentanyl, and 0.5 mg of pancuronium, and the tourniquet was immediately released after IV injection of the drugs. Patients in groups A–D underwent various elective operations on the forearm, wrist, and hand 10 min after IV injection.

Once the patient was in the operating room, a plastic intravenous cannula (20 gauge) was inserted in a distal vein of the affected hand, preferably on the dorsum. An infusion of IV fluid was commenced on the contralateral arm on which a blood pressure cuff was also applied. A bipolar lead II of the electrocardiogram was continuously monitored from the start of the procedure. The limb was then elevated for 5 min, and an Esmarch bandage was applied from the fingers proximally to reach a double-cuffed tourniquet applied on the upper arm. The proximal cuff was first inflated to 250–300 mm Hg with a constant-pressure pneumatic inflator. The Esmarch bandage was then removed, and 40 mL of a solution was injected intravenously. Once anesthesia was started in the limb, the distal cuff on the analgesic part was inflated, and the proximal one was deflated. Surgery was begun 10 min after injection of the drugs in groups A–D, whereas the tourniquet was immediately released after injection of the drugs in group E. All patients were monitored in the standard manner.

Intraoperative degree of analgesia was evaluated by the patient as well as by an observer using two different pain scores (16,17). Scores were assigned to the patient at 5-min intervals during surgery (Table 1). The subjective pain score (17) was explained to each patient on the day before surgery. To enhance its sensitivity, key descriptive phrases and pictures depicting facial expressions of pain or its absence were associated with the numbers on the score. For example, a 10 on the score was described as "pain is excruciating," whereas 0 was described as "no pain," with the midsection labeled as "moderate." Patients were instructed on the use of numerical responses to standard questions that would be asked of them with regard to skin incision and closure and intraoperative levels of pain associated with the surgical area. These instructions were reinforced preoperatively by the anesthesia staff on the day of surgery. Although different staff interviewed the patients, all instructions and questions were standardized.

Table 1. Objective Pain Scoring System

Score	Description	Feature
0	Excellent	Patient was completely pain free and lying quietly
1	Good	Patient was satisfied but experienced minor pain for a short period during surgery
2	Incomplete	Patient had significant pain relief but experienced minor pain during most of the time of surgery
3	Failure	Patient had no pain relief during most of the time of surgery
4	Excruciating	Surgery under general anesthesia

Sensation was tested by multiple pinpricks on the affected arm and by monitoring of neuromuscular blockade using train-of-four stimulation by applying four supramaximal stimuli (2 Hz) at intervals of 0.5 s over a period of 2 s at the ulnar nerve with surface electrodes. Complete neuromuscular blockade was determined by the disappearance of muscle twitch responses to train-of-four stimulation and was assessed by tactile and visual evaluation without recording equipment.

Testing for statistical significance was done using two-factor analysis of variance followed by the Mann-Whitney test and χ^2 analysis. A P value < 0.05 was considered significant.

Results

In all groups, there were no significant differences in age, body weight, height, gender, and general health. Likewise, surgical procedures performed on forearm, wrist, and hand in groups A–D were similar in type and included soft tissues, nerves, tendons, bone, and joints (Table 2). In addition, no significant difference in injection-release interval was found.

Intraoperative degree of analgesia was assessed similarly by the patient and the observer (Table 3, Figure 1). The analgesic effect was significant in group D compared with groups A–C. In 9 of 15 patients, analgesia was excellent. In six patients, minor pain was experienced only after start of surgery, and for 5 min thereafter patients were pain free and remained so 10 min postoperatively (Table 3). Pain sensation to pinprick in group D was abolished 5–10 min after drug injection and returned immediately after release of the tourniquet. In group A, analgesia was good in only two subjects and was incomplete in two others. Analgesia failed in eight subjects, mainly 10 min after start of surgery. Three subjects were changed to general anesthesia, two of them 10 min and the third 15 min after start of surgery owing to excruciating pain that could not be

Table 3. Objective Assessment of Level of Analgesia in Four Study Groups

Study group[a]	Level of analgesia					Successful analgesia [No. (%)]
	Excellent	Good	Incomplete	Failure	Excruciating	
A	0	2	2	8	3	2 (13.3)
B	0	4	1	8	2	4 (26.6)
C	0	1	7	5	2	1 (6.6)
D	9	6	0	0	0	15 (100)

[a] n = 15 in each group.

tolerated. In group B, analgesia was obtained successfully in 26.6% of subjects (Table 3). Analgesia was complete in four patients, and one patient with incomplete analgesia experienced minor pain during most of the surgery. Failure of analgesia was reported in eight cases, and general anesthesia was initiated in two patients 10–15 min after start of surgery. In group C, good analgesia was achieved in only one subject; it was incomplete in seven and failed in five others. In two patients, general anesthesia was necessary (Table 3). Operations on patients who had little pain relief for most of the surgery could be completed under IV block with the help of 5–10 mg of diazepam with or without IV meperidine. Neuromuscular blockade was profound in groups C and D compared with groups A and B. Complete abolition of twitch response and absence of spontaneous movements on command in groups C and D were achieved within 4–5 min after drug injection. Muscle power returned within 5–10 min after release of tourniquet.

With regard to safety, questioning of patients undergoing surgery did not reveal any toxic symptoms. In group E, all volunteers complained of mild dizziness; four developed visual disturbances starting 1 min and lasting 5–7 min after the release of the tourniquet. In another volunteer, vomiting and hypotension with systolic arterial blood pressure of 90 mm Hg occurred 5 min after release of tourniquet and returned to normal 5 min later without any IV fluid or drug administration. This volunteer's hemoglobin was 8.6 g/dL. In six subjects, there was some difficulty in moving the affected arm. This disappeared within 15 min. Another subject experienced heaviness in the eyelids and had difficulty opening his eyes. Sinus tachycardia developed in five subjects at 2 min and subsided by itself 5–10 min after release of tourniquet. In other five subjects, tachypnea was recorded 2 min after release of tourniquet and subsided 10 min later, except in one volunteer who remained tachypneic for 20 min and had chronic bronchitis and emphysema.

Discussion

Our preliminary investigation demonstrates the efficacy of the modified IV block developed at our institution, with the tourniquet conventionally placed

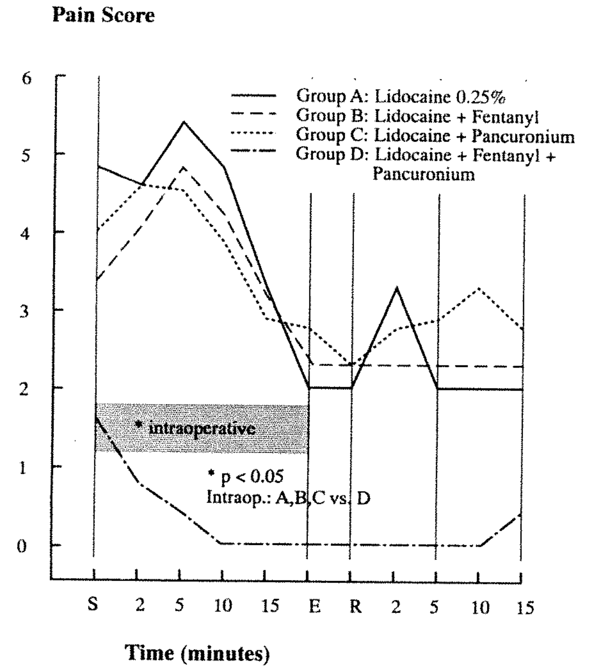

Figure 1. Subjective pain assessment in study groups A–D. R, release of tourniquet. E, end of surgery; S, start of surgery.

over the upper arm and with a dose of lidocaine comparable to the size of the bolus dose used for treating ventricular arrhythmias (13) or before endotracheal intubation (14). Analysis of data shows that the differences among the groups were clearly significant in group D. The patients rated their analgesia as good or excellent, and successful analgesia was achieved with a dose of no more than 100 mg of lidocaine. So far, adequate analgesia has been observed only with 0.5% lidocaine, suggesting that more dilute solutions do not appear to provide adequate analgesia (8,12,15). Accordingly, in group A with 0.25% lidocaine, heavy sedation or general anesthesia was required in eight patients. This high failure rate may have been reduced if our patients had been premedicated. The addition of 0.05 mg of fentanyl in group B significantly increased the quality of analgesia compared with group A, preserving the benefit of a low dose of local anesthetic. An additional advantage noted in our study using an upper arm tourniquet was complete muscle relaxation, which was very useful in certain operations such as those for tendolysis and proper fixation of bone fractures. The regional administration of muscle relaxants has been used for experimental, therapeutic, and diagnostic purposes (18,19).

The possible mechanism by which fentanyl enhances the action of lidocaine on peripheral nerve blockade is unclear. Although no in vivo studies have demonstrated a measurable local anesthetic effect of fentanyl, in vitro studies have shown that perineural fentanyl depresses the action potential in nerve fibers of different types (20,21). Recordings of fast-conducting A fibers and slow-conducting C fibers before and after exposure to 50 and 100 μg/mL of fentanyl indicate that a high concentration of fentanyl may partially suppress conduction in peripheral nerves and apparently does not diffuse well through a nerve sheath (20). Thus, it is unlikely that fentanyl per se would cause conduction blockade in vivo in peripheral nerves that are enclosed within a nerve sheath. Opioids are much more effective at blocking dull pain (C fibers) than acute pain (A-delta fibers). This agrees with the observation that the addition of fentanyl (50 μg/mL) to stable bupivacaine block significantly augments the effect, particularly of C fibers (21). Thus, labor and surgical pain are not completely blocked by opioids alone. The depressant effect of fentanyl on the action potential of A and C fibers in desheathed peripheral nerves is probably not related to the presence of opiate receptors in these nerves, because pretreatment with naloxone failed to inhibit the decrease in action potential produced by fentanyl (20). This also agrees with the observation that there is a virtual absence of opiate receptors in spinal ventral roots and in peripheral nerves (22). In this regard, evidence has been presented by various investigators that opiates may have a dual mechanism of action (23,24). The primary clinical effect is related to interaction with opiate receptors after epidural or intrathecal administration. On the other hand, fentanyl may cause some depression of nerve transmission similar to that produced by local anesthetics. This fact suggests that fentanyl may possess weak local anesthetic properties. It is possible that the addition of local anesthetics to fentanyl enhances its weak local anesthetic effect to such an extent that a clinical response can be observed as in group B. The success rate in group B would probably have been even higher in premedicated patients. However, the combination of the three drugs used in group D in our study improved the quality of analgesia and relaxation in such a way that upper limb surgery could be accomplished with success in all cases.

The safety of this modification was confirmed in group E by the absence of serious symptoms and signs of toxicity after release of tourniquet pressure immediately after injection of the drugs. In group E, only mild side effects attributable to the technique were noted. One person complained of transient hypotension associated with nausea after immediate deflation of the tourniquet. Thus, the low lidocaine dose used in group D represents a negligible risk in the event of accidental release of tourniquet pressure, with a further decreased risk with the addition of fentanyl and pancuronium, owing to the smaller dose of lidocaine used.

Therefore the combination of these drugs may prove to be a useful adjunct to IV regional anesthesia.

---

The present study compares the effectiveness of 0.25% ropivacaine and 0.25% bupivacaine in 44 patients receiving a subclavian perivascular brachial plexus block for upper extremity surgery. The patients were assigned to two equal groups in this randomized, double-blind study; one group received ropivacaine 0.25% (112.5 mg) and the other, bupivacaine 0.25% (112.5 mg), both without epinephrine. Onset times for analgesia and anesthesia in each of the C-5 through T-1 brachial plexus dermatomes did not differ significantly between the two groups. The mean onset time for analgesia ranged from 11.2 to 20.2 min, and the mean onset time for anesthesia ranged from 23.3 to 48.2 min. The onset of motor block differed only with respect to paresis in the hand, with bupivacaine demonstrating a shorter onset time than ropivacaine. The duration of sensory and motor block also was not significantly different between the two groups. The mean duration of analgesia ranged from 9.2 to 13.0 h, and the mean duration of anesthesia ranged from 5.0 to 10.2 h. Both groups required supplementation with peripheral nerve blocks or general anesthesia in a large number of cases, with 9 of the 22 patients in the bupivacaine group and 8 of the 22 patients in the ropivacaine group requiring supplementation to allow surgery to begin. In view of the frequent need for supplementation noted with both 0.25% ropivacaine and 0.25% bupivacaine, we do not recommend using the 0.25% concentrations of these local anesthetics to provide brachial plexus block.

(Anesth Analg 1992;75:602–6)

Ropivacaine is a new long-acting local anesthetic that is a chemical congener of bupivacaine and mepivacaine. In the initial studies in humans, 0.5% ropivacaine, both with and without epinephrine, provided effective sensory and motor blockade when used to provide brachial plexus anesthesia (1). More recently, a double-blind comparison of 0.5% ropivacaine with 0.5% bupivacaine demonstrated the two drugs to be similar in terms of both onset and duration of sensory and motor block and in terms of the incidence of analgesia, anesthesia, paresis, and paralysis (2).

Both bupivacaine and mepivacaine contain a chiral center and thus can exist as a pair of stereoisomers or enantiomers, currently designated as either *R*- or *S*-configurations (3). Nonetheless, both of these local anesthetics are prepared and used clinically as the racemate despite differences in the pharmacodynamics and pharmacokinetics of such enantiomers. The *S*-enantiomer is the principal agonist (the eutomer), because it possesses true local anesthetic activity, whereas the *R*-enantiomer (the distomer) not only possesses less local anesthetic activity, but greater toxicity (4–7). When ropivacaine, a congener of mepivacaine and bupivacaine, was considered as a replacement for bupivacaine in regional anesthesia, it was made available as the pure *S*-enantiomer, the assumption being that the use of the *S*-enantiomer would provide greater local anesthetic potency and less local anesthetic toxicity than the racemic mixture. Subsequently, animal data have indicated that ropivacaine does possess anesthetic properties that are very similar to those of its racemic relative, bupivacaine, but with considerably less anesthetic toxicity, particularly in terms of the cardiovascular system (6,7). Because ropivacaine is the pure *S*-enantiomer, and bupivacaine is the racemic mixture of the *R*- and *S*-enantiomers, ropivacaine should have greater anesthetic potency (i.e., a lower concentration of ropivacaine might have the anesthetic potency of a higher concentration of bupivacaine). A small, open, pilot study undertaken by two of the authors in a small

0003-2999/92/$5.00

group of five patients undergoing upper extremity surgery indicated that 0.25% ropivacaine provided excellent surgical anesthesia in all five patients.

The purpose of the present study is to expand on that pilot study and to compare the anesthetic characteristics of this concentration of ropivacaine with those of 0.25% bupivacaine when used for brachial plexus block using the subclavian perivascular approach.

Methods

This study was designed as a randomized, double-blind, parallel-group clinical trial. The institutional review boards at both institutions provided approval before initiation of the study, and all patients gave informed consent before being included. The 44 patients selected for inclusion were ASA physical status I and II and were scheduled to undergo elective surgery on the upper extremity under brachial plexus block anesthesia. Excluded from the study were patients with a history of allergy to amide local anesthetics and women who were pregnant.

The patients were randomly assigned to two equal groups on the basis of the local anesthetic to be utilized, so that 22 patients received 0.25% ropivacaine without epinephrine and 22 patients received 0.25% bupivacaine, also without epinephrine. The same protocol was followed at each institution. All of the patients were unpremedicated until they arrived in the operating room, at which time midazolam was titrated intravenously to a maximum of 3.0 mg to relieve anxiety before administration of the block. Each patient then received a subclavian perivascular block according to the technique previously described by Winnie (8). After a paresthesia radiating to a point below the shoulder had been elicited and aspiration for blood was negative, 3 mL of the study drug was injected rapidly to produce a "pressure paresthesia" to confirm proper placement of the needle. The remaining 37 mL was then injected over a period of approximately 1 min, with aspiration repeated every 5 mL. The intercostobrachial and medial brachial cutaneous nerves were then blocked separately by a subcutaneous injection of 5 mL of the study drug superficial to the axillary artery. In any given case, if after the injection of the study drug there was inadequate analgesia for the surgical procedure, appropriate supplemental nerve blocks were performed or general anesthesia was induced. Whenever supplementary nerve blocks were required, data were included only from those dermatomes that exhibited blockade before the supplemental blocks.

Evaluation of sensory and motor function was performed before the administration of the block and then at 2, 5, 10, 15, 20, 25, and 30 min after the block. For the next 5 h, sensory and motor function were evaluated every 15 min, for the subsequent 7 h every 30 min, and then every 60 min until recovery was complete. Sensory function was assessed in the C-2 through T-2 dermatomes and graded such that no loss of sensation to pinprick was scored as 0, analgesia (patient feels touch but not pinprick) was scored as 1, and anesthesia (patient does not even feel touch) was scored as 2. Motor block was assessed at the shoulder by asking the patient to elevate the arm while keeping the elbow straight to evaluate the degree of blockade of the superior trunk and at the hand by determining the strength of handgrip to evaluate the degree of blockade of the middle and inferior trunks. Motor function was graded such that no weakness was scored as 0, paresis was scored as 1, and paralysis was scored as 2.

Table 1. Clinical Characteristics of 44 Patients Undergoing Upper Extremity Surgery

Study group	Age (yr)	Height (cm)	Weight (kg)	Gender (M/F)
Ropivacaine 0.25%	43 ± 15	173 ± 11	78 ± 20	19/3
Bupivacaine 0.25%	44 ± 14	174 ± 9	79 ± 17	19/3

M, male; F, female.
Mean ± SD.

In addition to sensory and motor function, heart rate and arterial blood pressure were monitored and recorded before premedication; before administration of the block; 2, 5, 10, 15, 20, 25, 30, 45, and 60 min after the block; and then every 30 min for an additional 2 h. Any signs or symptoms of central nervous system toxicity or any other adverse experiences were also recorded.

For statistical analysis of the data, continuous variables such as onset and duration of analgesia, anesthesia, paresis, and paralysis were tested using a Wilcoxon rank sum test. Binary variables, such as the presence or absence of sensory or motor block, were analyzed with the χ^2 test or Fisher's exact test. A P value of ≤0.05 was considered to represent statistical significance.

Results

There was no significant difference between the two groups of patients in terms of age, height, weight, or male/female ratio (Table 1). The frequency of analgesia in the C-2 through T-2 dermatomes did not significantly differ between the 0.25% ropivacaine and 0.25% bupivacaine groups: 76% or more of the patients in both groups developed analgesia in the C-5 through T-1 dermatomes of the brachial plexus, whereas few patients developed analgesia in the C-2

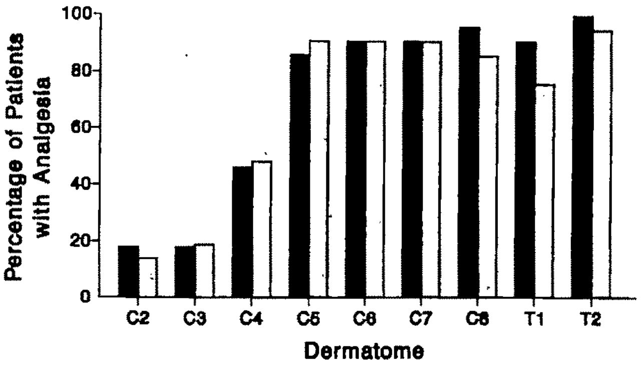

Figure 1. The frequency of analgesia was 76% or greater in the C-5–T-1 brachial plexus dermatomes and did not differ significantly between the 0.25% ropivacaine (■) and 0.25% bupivacaine (▨) groups. Few patients developed cervical plexus (C-2–C-4) analgesia.

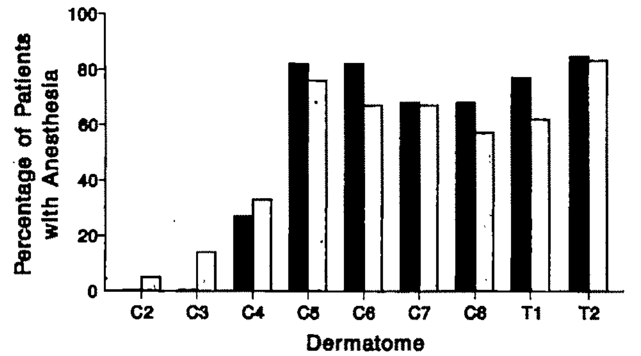

Figure 2. The frequency of anesthesia in the C-5–T-1 brachial plexus dermatomes ranged from 57% to 82% and did not differ significantly between the 0.25% ropivacaine (■) and 0.25% bupivacaine (▨) groups. Anesthesia developed infrequently in the cervical plexus (C-2–C-4).

through C-4 dermatomes of the cervical plexus (Figure 1). There was no significant difference between the two groups with respect to the frequency of anesthesia in the C2 through T-2 dermatomes: 57%–82% of the patients in both groups developed anesthesia in the C-5 through T-1 dermatomes of the brachial plexus, and again, only a small percent of patients developed anesthesia in the C-2 through C-4 dermatomes of the cervical plexus (Figure 2).

The onset times for analgesia and anesthesia also did not differ significantly between the ropivacaine and bupivacaine groups (Table 2). The mean onset time for analgesia ranged from 12.0 to 19.7 min for ropivacaine and 11.2 to 20.2 min for bupivacaine, whereas the mean onset time for anesthesia ranged from 23.7 to 48.2 min for ropivacaine and 23.3 to 47.1 min for bupivacaine. The duration of analgesia and anesthesia also did not differ significantly between the two groups, with a mean duration of analgesia ranging from 9.2 to 13.0 h and a mean duration of anesthesia ranging from 5.0 to 10.2 h (Table 3).

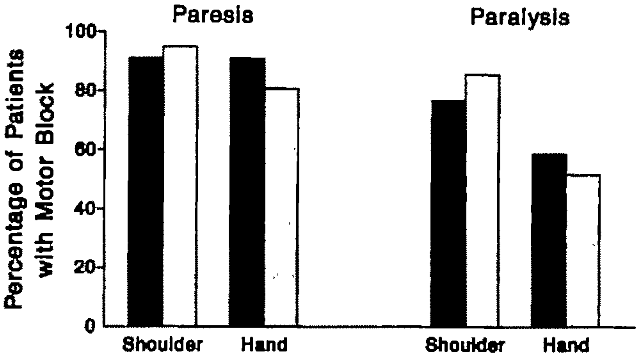

Figure 3. There was no significant difference between the 0.25% ropivacaine (■) and 0.25% bupivacaine (▨) groups in the frequency of motor block of any degree (paresis/paralysis of the hand and shoulder). Although motor paresis of the shoulder and hand was frequent (>80% of patients), paralysis of the hand was less common (52%–59% of patients).

Paresis of the shoulder and hand muscles developed in >80% of patients in both groups, whereas complete paralysis was less frequent (Figure 3). There was no significant difference between groups in the frequency of paresis or paralysis of either the shoulder or hand (Figure 3). Similarly, the onset and duration of motor block did not differ between groups (Table 4) except for the onset of paresis in the hand, which was significantly faster in the bupivacaine group.

Nine patients in the bupivacaine group and eight patients in the ropivacaine group required supplemental blocks or general anesthesia. The specific types of supplemental blocks used are listed in Table 5. One patient in the bupivacaine group was excluded from the analysis of efficacy because of a deviation from the protocol. Three patients in each group had Horner's syndrome, and one patient in each group experienced tourniquet pain. There were no significant differences between the two groups with respect to changes in systolic or diastolic blood pressure, heart rate, mean arterial pressure, or rate-pressure product at any time during the study.

Discussion

The efficacy of 0.25% ropivacaine for brachial plexus anesthesia was virtually identical to that of 0.25% bupivacaine in terms of onset and duration of sensory block as well as the need for supplementation. However, the 0.25% concentration of both agents appears to be unsuitable for brachial plexus block because of a high failure rate. The supplementation rate of 36% for the ropivacaine group and 43% for the bupivacaine group is in sharp contrast to the supplementation rate

Table 2. Onset of Sensory Block

	Onset of analgesia (min)		Onset of anesthesia (min)	
Level	Ropivacaine 0.25%	Bupivacaine 0.25%	Ropivacaine 0.25%	Bupivacaine 0.25%

[a] $P < 0.05$.

of 8% for both local anesthetics when used in a 0.5% concentration (2) observed in a previous study. The high rate of supplementation noted for the 0.25% concentrations appears to be due to the fact that this concentration is borderline with respect to the threshold necessary to develop anesthesia; for, although the incidence of analgesia in the C-5 through T-1 dermatomes ranged from 76% to 96%, the incidence of anesthesia in these dermatomes was much less. Likewise, although motor paresis at the shoulder and hand frequently developed (in >80% of all patients), complete motor paralysis was frequently not seen (in the hand 59% and 52%, respectively, for ropivacaine and bupivacaine).

The main advantage of ropivacaine over bupivacaine is its lesser potential for cardiac toxicity. In isolated rabbit Purkinje fiber ventricular muscle preparations, Moller and Covino (9) demonstrated that the effect of ropivacaine on altering various electrophysiologic variables was greater than lidocaine but less than bupivacaine. Feldman et al. (7) demonstrated in a dog model that although the convulsive doses of ropivacaine and bupivacaine were similar, ropivacaine was less arrhythmogenic than bupivacaine. Other animal studies have confirmed the lower cardiac toxicity of ropivacaine compared with bupivacaine (6,10,11). The one human study that has examined the acute toxicity of ropivacaine was reported by Scott et al. (12) in a group of 12 volunteers who received intravenous infusions of ropivacaine and bupivacaine up to a maximal dose of 150 mg. It was noted that ropivacaine caused less central nervous system symptoms and could be tolerated at a larger total dosage than bupivacaine (12). In addition, electrocardiogram and echocardiogram evidence of depression of conductivity and contractility appeared at smaller dosage and lower plasma concentrations with bupivacaine than with ropivacaine (12). In our study, we noted no overt signs of cardiac or central nervous system toxicity with either bupivacaine

Table 5. Number of Patients Requiring Supplementation of Anesthesia and Analgesia

Local infiltration		1

(0.89–2.0 mg/kg) or ropivacaine (0.81–2.3 mg/kg). In the two previous brachial plexus studies reported with slightly higher doses (up to 3.2 mg/kg of bupivacaine and 3.1 mg/kg of ropivacaine), there was also no evidence of toxicity. It should be noted, however, that in each of these studies, the patients were premedicated with midazolam, which could increase the threshold, at least for central nervous system toxicity. In addition, unlike the volunteers studied by Scott et al. (12), our patients did not undergo formal electrocardiogram analysis or echocardiographic studies to determine more subtle signs of cardiac toxicity.

In conclusion, we have demonstrated that for subclavian perivascular brachial plexus block, despite theoretical potency of ropivacaine because of exclusion of the less potent *d*-isomer, 0.25% ropivacaine is similar in quality to 0.25% bupivacaine in most aspects. Both local anesthetics, however, are frequently associated with inadequate sensory or motor block, or both. In view of the high rate of supplementation necessary with both 0.25% ropivacaine and 0.25% bupivacaine, we recommend using the 0.5% concentration of these local anesthetics to provide brachial plexus anesthesia.

Epidural Clonidine Enhances Postoperative Analgesia From a Combined Low-Dose Epidural Bupivacaine and Morphine Regimen

Torben Mogensen, MD, Kirsten Eliasen, MD, Ellen Ejlersen, MD, Palle Vegger, MD, Ingrid K. Nielsen, MD, and Henrik Kehlet, MD, PhD

---

In a randomized, double-blind, placebo-controlled trial, the value of adding clonidine to a low-dose epidural regimen for postoperative pain treatment was assessed. Twenty-four patients scheduled for hysterectomy during combined thoracic epidural (bupivacaine and morphine) and general anesthesia were studied. Postoperative analgesia consisted of epidural bupivacaine (5 mg/h) and morphine (0.1 mg/h) for 12 h. In addition, the patients randomly received clonidine (75 μg), followed by an infusion of 18.75 μg/h or saline solution (placebo) epidurally. Pain was evaluated at rest, during cough, and during mobilization every hour. Sensory level of analgesia was evaluated by pinprick. We found no significant difference in pain scores at rest between the clonidine and placebo groups but an enhanced analgesic effect by clonidine during cough and mobilization ($P < 0.05$). Arterial blood pressure decreased significantly during clonidine infusion and remained lower than in the control group throughout the study. We conclude that a continuous low-dose epidural clonidine infusion enhances analgesia from a combined low-dose epidural bupivacaine and morphine regimen after hysterectomy; however, the concomitant decrease in arterial blood pressure during epidural clonidine deserves further study before such a regimen can be recommended.

(Anesth Analg 1992;75:607–10)

Despite developments in the treatment of postoperative pain, many patients still have pain after surgery (1). The explanation hereto may be lack of an effective postoperative pain treatment regimen without side effects. We have previously advocated the principle of multimodal pain therapy ("balanced analgesia") based on the hypothesis that a combination of analgesics with different sites of action may improve overall pain relief (2). Epidural administration of combined local anesthetics and opioids may provide improved pain relief but still carries the risk of side effects when doses approach levels necessary for total pain relief (3–8). Clonidine, an α_2-adrenergic agonist, reduces but does not eliminate pain after surgery (9–12). The mechanism of pain relief seems to be different from that of opioids, because it can be antagonized by phentolamine but not naloxone (13). However, with the relatively high doses of clonidine used in clinical investigations, significant hemodynamic depression with hypotension was observed (9–12).

The aim of this study was to evaluate the effect of adding low-dose clonidine to a very low-dose regimen of continuous epidural local anesthetics and morphine on pain relief and arterial blood pressure after hysterectomy.

Methods

A randomized, placebo-controlled, double-blind trial was designed in agreement with the Helsinki II Declaration. The study was approved by the regional ethical committee and the Danish Health Service, and informed consent was obtained from each patient.

Twenty-four patients scheduled for abdominal hysterectomy were premedicated with diazepam (0.2 mg/kg). Before induction of general anesthesia, a 20-gauge epidural catheter was inserted between T-10 and T-11 and 3 mL of plain (0.5%) bupivacaine as a test dose, followed by 5 mL of plain (0.5%) bupivacaine plus 1 mg of morphine (2.5 mL of 0.4 mg/mL) was used to produce epidural analgesia. General anesthesia was induced with thiopental (3–5 mg/kg

0003-2999/92/$5.00

IV). After pancuronium (0.01 mg/kg IV), succinylcholine (1.5 mg/kg) was used to facilitate orotracheal intubation. General anesthesia was maintained with N_2O/O_2 (2:1) and isoflurane (0.5%–1.5%).

Postoperative pain treatment consisted of epidural 0.125% bupivacaine (4 mL/h) and morphine (0.1 mg/h) initiated 30 min after the initial dose of bupivacaine and morphine had been administered and scheduled for 12 h, delivered by a Pharmacia Deltec infusion pump. The patients were randomized to receive in a double-blind fashion either clonidine (75 μg) dissolved in 3 mL of saline solution immediately after the initial dose of bupivacaine and morphine, followed by 18.75 μg/h together with the infusion of bupivacaine and morphine for 12 h (group I) or saline solution (group II). The volume of the epidural infusion was 4 mL/h in both groups. On request, the patients received supplemental morphine (0.15 mg/kg) intramuscularly.

Pain was evaluated by one of the authors every 2 h at rest, during cough, and during mobilization from the supine to the sitting position in bed by a 10-cm visual analogue scale and verbal rate scoring (0 = no pain, 1 = slight pain, 2 = moderate pain, 3 = severe pain, and 4 = unbearable pain). Sensory level of analgesia was evaluated by pinprick. Blood pressure was measured every hour. Ephedrine was administered if systolic arterial blood pressure decreased to below 80 mm Hg.

Results are expressed as median values and ranges. A Mann-Whitney test for unpaired data was used to compare the two groups. Because the trial design implied multiple intraperson assessments of pain over time, the relevant statistical method was analysis of variance. Because of ordinal measurements, we used the corresponding nonparametric method in which treatments were compared with the Mann-Whitney test for unpaired data disregarding time, and both the factor time and the interaction between time and treatment were assessed by Friedman's test; $P < 0.05$ was considered significant (14).

Results

Two patients, one from each group, were excluded from the study because of displacement of the epidural catheter, and the study thus comprised 22 patients. There were no differences in demographic data between the two groups (Table 1). Median visual analogue scale and verbal rate scores at rest, during cough, and during mobilization are shown in Figure 1. There was no significant difference between groups I and II at rest, in contrast to significantly higher pain scores during cough and mobilization in the saline solution group ($P < 0.05$). The supplemental intramuscular doses of morphine in groups I and II were, respectively, 0 mg (0–10) and 0 mg (0–20) [median (range)]; $P > 0.05$.

Table 1. Demographic Data of Patients Undergoing Abdominal Hysterectomy

	Epidural + clonidine group (n = 11)	Epidural + placebo group (n = 11)
Age (yr)	46 (34–52)	47 (35–65)
Weight (kg)	57 (53–80)	60 (54–75)
Height (cm)	167 (157–180)	167 (159–173)
Duration of surgery (min)	120 (70–180)	105 (55–150)

Median (range); P = NS.

The frequency of patients with no pain (verbal rate score = 0) experienced during cough during the 12-h period in group I was 45% compared with 9% in group II; the median difference between groups was 36% (95% confidence interval 2%–70%).

No decrease in sensory level of analgesia was seen during the 12-h period, and there was no difference between the groups ($P > 0.05$) (Figure 2). There was a significant decrease in arterial blood pressure in the clonidine-treated patients (group I) compared with the initial value ($P < 0.05$) (Figure 3). The amount of supplemental ephedrine during surgery was 10 mg (0–50) in group I and 0 mg (0–50) in group II; after surgery, 0 mg (0–25) in group I and 0 mg (0–10) in group II; and totally, 10 mg (0–50) in group I and 0 mg (0–50) mg in group II [median (range)]; $P > 0.05$. No respiratory complications indicating treatment were seen.

Discussion

The use of epidural local anesthetics in combination with morphine is one of the most powerful methods to produce postoperative pain relief. However, there is significant risk for serious side effects, such as respiratory depression, hypotension, and urinary retention, when doses necessary to produce total pain relief are used (7,8). When the doses of morphine and local anesthetics are reduced, the number of side effects may decrease but at the risk of inadequate pain relief (5,6). Therefore, there is a need for new approaches to the treatment of severe, acute pain. We have previously advocated the term "balanced analgesia" (i.e., a combination of low doses of different drugs having different antinociceptive characteristics) (2,15), with the goal of increasing pain relief and reducing the side effects.

The α_2-agonists, like clonidine, probably activate postsynaptic receptors at noradrenergic pathways involved in endogenous pain control (16), both in

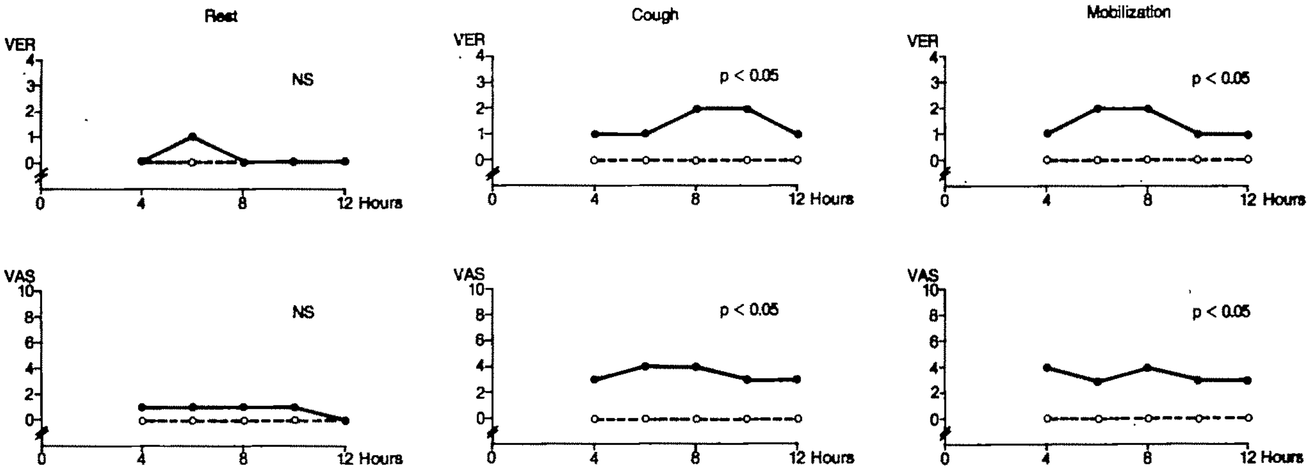

Figure 1. Median postoperative pain scores during rest (*left*), cough (*middle*), and mobilization (*right*) during continuous epidural bupivacaine (5 mg/h) and morphine (0.1 mg/h) plus epidural clonidine (18.75 $\mu g/h$) (—O—) ($n = 11$) or placebo (—●—) ($n = 11$) after hysterectomy. Significant difference ($P < 0.05$) at cough and mobilization. VER, verbal rate score; VAS, visual analogue scale.

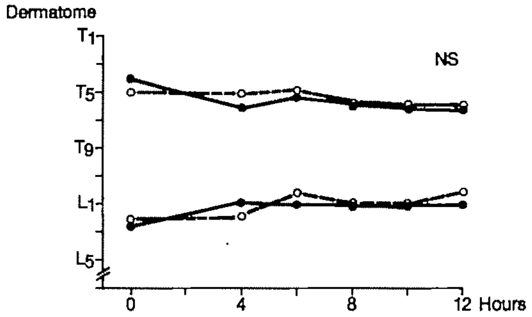

Figure 2. Median sensory level of analgesia (pinprick) during continuous epidural bupivacaine (5 mg/h) and morphine (0.1 mg/h) plus epidural clonidine (18.75 $\mu g/h$) (—O—) ($n = 11$) or placebo (—●—) ($n = 11$) after hysterectomy ($P > 0.05$).

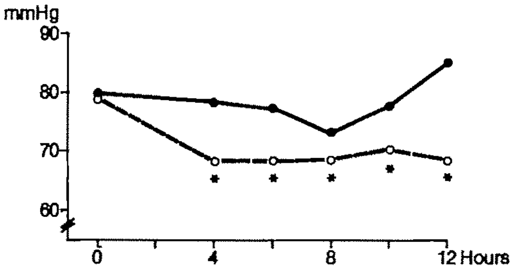

Figure 3. Median arterial blood pressure during continuous epidural bupivacaine (5 mg/h) and morphine (0.1 mg/h) plus epidural clonidine (18.75 $\mu g/h$) (—O—) ($n = 11$) or placebo (—●—) ($n = 11$) after hysterectomy. $^*P < 0.05$ compared with initial value; $P < 0.05$ between the treatments.

the dorsal horn of the spinal cord (17) and at the supraspinal level (18). This effect is different from both opioids and local anesthetics. The difference in analgesic effect of clonidine after intramuscular or epidural administration may be none or small (12).

Clonidine has been shown in most (9–12), but not all (19), studies to have beneficial effects on postoperative pain. Because clonidine in experimental studies may have very low neural toxicity after intrathecal administration (20), we added a low dose of clonidine to a very low-dose continuous epidural local anesthetic and morphine regimen to improve pain relief.

Our results demonstrate that epidural clonidine (75 μg) followed by an infusion of 18.75 $\mu g/h$ enhances postoperative analgesia of a very low-dose epidural bupivacaine and morphine regimen. These results are in accordance with the results from experimental studies in which a synergistic or additive analgesic effect of α_2-agonists and morphine (21,22) has been demonstrated. A synergistic/additive analgesic effect has also been demonstrated with the combination of local anesthetics and clonidine (23,24).

In most studies, clonidine has been administered by a bolus dose injection, resulting in analgesia lasting from 2 to 5 h (9,10,12). The short duration of the drug makes continuous infusion more suitable for postoperative pain relief compared with bolus injection. A continuous infusion may also result in lower peak concentrations in plasma and cerebrospinal fluid, thereby possibly reducing side effects. However, even with our relatively small dose of clonidine, we found a decrease in arterial blood pressure comparable to that observed in studies in which bolus injections were used (9,10,22). Therefore, further studies are needed to evaluate the optimal dose regimen of clonidine with regard to pain relief versus hemodynamic side effects.

In conclusion, we found an increase in analgesia at cough and mobilization when clonidine was added to a continuous low-dose epidural infusion of bupivacaine and morphine. However, the concomitant decrease in arterial blood pressure calls for further studies before such a regimen can be recommended for daily clinical practice.

We thank the department secretary Nina Meier for typing the manuscript.

Lidocaine and Bupivacaine Cardiorespiratory Toxicity Is Additive: A Study in Rats

Berend Mets, FFARCS(Eng), FFA(SA), Piotr K. Janicki, MD, PhD,
Michael F. James, FFARCS(Eng), PhD, Richard Erskine, FFA(SA), and Brian Sasman

Anglo American Corporation Anaesthetic Research Laboratory, and Department of Anaesthesia, University of Cape Town Medical School, Observatory, Cape Town, South Africa

The purpose of this study was to determine whether equipotent solutions of lidocaine, bupivacaine, or a mixture of these compounds infused at a fixed rate in anesthetized rats resulted in equivalent lethal cardiorespiratory toxicity and to establish whether the lethality of the individual drugs was additive. This was assessed by comparing the time to respiratory and circulatory arrest, determining the lethal doses of administered local anesthetic in each group, and ascertaining the concentration of lidocaine or bupivacaine, or both, at the time of circulatory arrest. The times to respiratory and circulatory arrest were similar in rats receiving either lidocaine (2%) or bupivacaine (0.5%) or a mixture of 1% lidocaine and 0.25% bupivacaine. The mean lidocaine-to-bupivacaine cumulative lethal dose ratio (3.36) and concentration ratio (2.33) were determined and used to calculate lidocaine equivalent values for bupivacaine data. Lidocaine equivalent cumulative lethal doses and plasma concentrations were similar in all three groups studied. This work suggests that the lethal cardiorespiratory toxicity of lidocaine and bupivacaine associated with intravenous infusion is additively toxic in rats.

(Anesth Analg 1992;75:611–4)

Different local anesthetics are often combined with advantage in clinical practice (1). The combined toxicity of local anesthetic (LA) mixtures has been investigated in animal studies with conflicting results; synergistic toxicity (2), additive toxicity (3), as well as antagonism of toxicity at higher doses (4), have all been found. Lidocaine and bupivacaine mixtures after subcutaneous administration have been studied in mice and were found to be essentially additive in toxicity and marginally less toxic than the individual compounds (5).

Our purpose was to determine whether a mixture of bupivacaine and lidocaine was also additively toxic when administered intravenously, the preferred method for assessing LA toxicity (6). In addition to assessing this by determining the time to respiratory and circulatory arrest on infusion of the individual compounds as well as the mixture, we wanted to determine whether the lethal doses and lethal plasma concentrations of these drugs were also additive.

Methods

Seventy-one male Long-Evans rats weighing app
imately 360 g were studied with institutional
proval and anesthetized with intraperitoneal pe
barbital (60 mg/kg). Cutdowns were performed i
groin to place right femoral artery and left fe
vein catheters, each 10 cm in length (19 gauge B
cath, Sheffield, England). The arterial catheter
used to measure arterial blood pressure continuo
and display the arterial waveform by means o
oscilloscope set on a scale of 0–300 mm Hg,
a sweep speed of 25 mm/s while the heart
and rhythm were continuously monitored wit
electrocardiogram (ECG). The venous catheter
connected to a calibrated infusion pump for
ministration of the test solution at a rat
0.16 $\text{mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$. Eleven animals received s
solution (group S), and 60 animals were rand
allocated to receive commercially available lidoc
hydrochloride (2%) at 3.2 $\text{mg}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ (grou
bupivacaine hydrochloride (0.5%) at 0.8 mg·k
min^{-1} (group B), or a mixture of lidocaine (

Mean (±SE) baseline weights, duration of anesthesia before start of experiments (anesthetic time), mean arterial pressure, respiratory rate, and arterial blood gas data for rats that received saline solution (group S, $n = 11$); 2% lidocaine (group L, $n = 20$); 0.5% bupivacaine (group B, $n = 22$); and 1% lidocaine and 0.25% bupivacaine (group BL, $n = 18$); P = NS.

diurnal variations, and the rats were neither oxygenated nor ventilated.

Approximately 35 min after the start of the anesthetic, the time was noted, and baseline measurements of respiratory rate and mean arterial pressure were performed; 0.4 mL of blood was drawn for arterial blood gas analysis. The test solution was then infused from time zero, and the time to cessation of visible respiratory excursion (respiratory arrest) as well as circulatory arrest, defined as an absence of arterial pulsation on the oscilloscope for one screen width, was noted. At this time, the cardiac rhythm on the ECG was noted, the infusion terminated, and a blood sample obtained by direct cardiac puncture for the determination of plasma lidocaine or bupivacaine concentrations, or both. This was determined in triplicate by means of gas chromatography with a method adapted from Tucker (7). The deviation from the expected value ($n = 9$) was 9.6% for bupivacaine and 8.6% for lidocaine over the range 10–50 μg/mL.

Data were analyzed with one-way analysis of variance and the Tukey multiple-range test to determine differences among the groups. A P value of <0.05 was regarded as significant. Results are presented as mean (±SEM).

Table 2. Time to Respiratory and Circulatory Arrest

Respiratory arrest (min)	—	11.6 (0.7)	14.4 (1.4)	14.0 (1.4)
Circulatory arrest (min)	—	12.9 (0.6)	15.6 (1.5)	15.1 (1.4)
Respiratory to circulatory arrest (min)	—	1.35 (0.1)	1.1 (0.1)	1.1 (0.1)

Mean (±SE) times to respiratory and circulatory arrest for rats that received 2% lidocaine (group L, $n = 20$); 0.5% bupivacaine (group B, $n = 22$); and 1% lidocaine and 0.25% bupivacaine (group BL, $n = 18$); P = NS.

Table 3. Cumulative Dose of Local Anesthetic at Time of Circulatory Arrest

	Group L	Group B	Group BL
Lidocaine (mg/kg)	41.3 (2.1)	—	24.2 (2.2)
Bupivacaine (mg/kg)	—	12.3 (1.1)	6.1 (0.6)
Lidocaine equivalent (mg/kg)[a]	41.3 (2.1)	41.3 (3.8)	44.6 (4.1)

Mean (±SE) local anesthetic and lidocaine equivalent cumulative doses at time of circulatory arrest for rats that received 2% lidocaine (group L, $n = 20$); 0.5% bupivacaine (group B, $n = 22$); and 1% lidocaine and 0.25% bupivacaine (group BL, $n = 18$).

[a] Lidocaine equivalent doses calculated from a lidocaine/bupivacaine lethal dose ratio of 3.36 (see text). Lidocaine equivalent dose in group BL not significantly different from groups B and L.

Results

The four groups of rats were studied at equivalent times after the administration of anesthesia and were similar in weight and had similar mean arterial pressures, respiratory rates, and acid-base status at baseline before the administration of the test solution (Table 1). No control animal infused with saline solution died as a result of the methodology used. The times to respiratory and circulatory arrest were similar in the rats receiving lidocaine, bupivacaine, or a mixture containing half the amount of the individual compounds (Table 2) at standard infusion rates. The ECG monitoring revealed that after respiratory arrest, a supraventricular or ventricular tachycardia usually occurred, accompanied by a rapid decrease in arterial blood pressure. Circulatory arrest occurred ±1 min later (Table 2) and was accompanied by a broad complex agonal rhythm on ECG.

Table 3 shows the cumulative doses of lidocaine and bupivacaine at circulatory arrest. By using the mean data for lidocaine and bupivacaine administered separately, the lidocaine/bupivacaine cumulative dose ratio at the time of circulatory arrest could be determined (3,5) and was found to be 3.36. To facilitate the interpretation of results with mixtures, the lidocaine equivalent dose of bupivacaine at circulatory arrest (5) for each individual experiment could thus be calculated by using this factor.

The same methodology was also used to determine lidocaine equivalent plasma concentrations (Ta-

Table 4. Plasma Local Anesthetic Concentration at Time of Circulatory Arrest

	Group L	Group B	Group BL
Lidocaine (μg/mL)	289.1 (31.5)	—	134.9 (14.0)
Bupivacaine (μg/mL)	—	123.9 (9.3)	88.4 (6.6)
Lidocaine equivalent (μg/mL)[a]	289.1 (31.5)	288.6 (21.4)	338.2 (23.2)

Mean (±SE) local anesthetic and lidocaine equivalent concentrations at time of circulatory arrest for rats that received 2% lidocaine (group L, n = 20); 0.5% bupivacaine (group B, n = 22); and 1% lidocaine and 0.25% bupivacaine (group BL, n = 18).

ble 4). Lidocaine equivalent cumulative doses (Table 3) and plasma concentrations (Table 4) at time of circulatory arrest were similar when data for either of the individual compounds were compared with those for the lidocaine and bupivacaine mixture.

Discussion

This study in rats indicates that with regard to lethal cardiorespiratory depression, an equipotent mixture of lidocaine and bupivacaine is no more toxic than the individual compounds. The times to respiratory and circulatory arrest were similar in the three groups studied, as were the cumulative lethal doses and concentrations expressed in lidocaine equivalent values.

This study was designed to assess the effect of intravenous injection of clinically used concentrations of LAs administered individually or as a mixture in rats that were neither oxygenated nor ventilated to mimic the inadvertent intravenous injection or very rapid absorption of LAs in the clinical situation.

The purpose of this study, however, was not to establish individual organ system toxicities (i.e., central nervous system, respiratory, or cardiovascular toxicity for LAs) nor to investigate the mechanism of death, but rather to determine whether LAs administered intravenously individually or as a mixture had the same lethal potential. We took as the endpoint for this investigation the time to circulatory arrest rather than electrical asystole, because this would have resulted in falsely elevated values for the lethal LA concentrations, owing to the absence of hepatic blood-flow-dependent metabolism of continuously infused drug.

Death was most likely precipitated by respiratory arrest, and circulatory arrest was probably due to a combination of hypoxia, acidosis, and LA toxicity. Because an agonal rhythm persisted on ECG monitoring in the absence of a detectable arterial pressure waveform, the terminal event was probably acute cardiac failure rather than cardiac standstill. Convulsions that are a common feature of LA toxicity (3,5) were witnessed in only a single rat from group B. The lack of this toxic manifestation in our experiments can probably be attributed to the use of pentobarbital for anesthesia.

Lidocaine (2%) and bupivacaine (0.5%) were separately infused at equipotent (8) concentrations that were also in proportion to their lethal dose ratio in mice (8) and dogs (9). This proportion was maintained when these concentrations of LAs were mixed, thus achieving a final equipotent concentration of lidocaine (1%) and bupivacaine (0.25%) in the administered mixture. This methodology was adopted so that standard volumes of solution (0.16 mL/kg) were infused in all groups.

Intravenous administration is the most suitable route for assessing the toxicity of LAs, because it avoids the influence of various kinetic factors (e.g., drug permeability through tissue-blood barriers) (6). The toxicity of an LA depends on the plasma concentration but more specifically on the free fraction (10). During continuous infusion of an LA at a fixed rate, the plasma concentration depends on the rate of metabolism, and because lidocaine is more rapidly metabolized than bupivacaine in humans (11), the combination of these drugs may be less toxic than an equipotent infusion of bupivacaine. On the other hand, McNamara et al. (12) showed an increase in the free fraction of lidocaine in the presence of bupivacaine at clinical concentrations in vitro, which suggests that the combined administration of these drugs might be more toxic. The similar times for respiratory and circulatory arrest in the three groups studied (Table 2) suggest that the effect on LA toxicity of the previously mentioned two opposing kinetic factors may have balanced out when the two LAs were administered as a mixture.

The cumulative lethal dose ratio for lidocaine to bupivacaine of 3.36 determined in this study was less than the proportion of these drugs in the infused anesthetic mixture, which was based on a lethal dose ratio of 4:1 established in mice (8) and dogs (9). This is probably reflected in the nonsignificant tendency for earlier cardiorespiratory arrest in group L (Table 2).

This study allowed a comparison of the toxic concentrations at the time of circulatory arrest and is the first study to assess this for a mixture of lidocaine and bupivacaine. There was no statistical difference in the lidocaine equivalent concentrations at the time of circulatory arrest in those rats receiving the mixture compared with those receiving the individual drugs, suggesting that, independent of kinetic factors, lidocaine and bupivacaine are additively toxic (Table 4).

It is noteworthy that the cumulative lethal dose ratio (3.36) was significantly more than the lethal plasma concentration ratio of 2.33 ($P = 0.01$). This difference is probably due to pharmacokinetic differences, such as the more rapid elimination of lidocaine with respect to bupivacaine, as discussed earlier.

The limited number of investigations into the combined toxicity of LAs administered as mixtures were not directly comparable with the present study, because these investigated different LA mixtures in mice (2,4), rats (13), and monkeys (3). The only other study (5) that investigated the use of lidocaine and bupivacaine combined studied this in mice after subcutaneous administration of solutions mixed in proportion to their convulsive concentration. These authors concluded that this mixture was no more toxic than the individual drugs.

In conclusion, our work in rats suggests that the lethal cardiorespiratory toxicity of lidocaine and bupivacaine associated with intravenous infusion is additive.

Noninvasive Percutaneous Induction of Topical Analgesia by a New Type of Drug Carrier, and Prolongation of Local Pain Insensitivity by Anesthetic Liposomes

M. E. Planas, MD, P. Gonzalez, MD, L. Rodriguez, MD, S. Sanchez, MD, and G. Cevc, PhD

Department of Pharmacology and Therapeutic Chemistry, University of Barcelona, Faculty of Odontology, Hospitalet de Llobregat, Barcelona, Spain, and Medizinische Biophysik-Forschungslaboratorien, Urologische Klinik und Poliklinik der Technischen Universität München, Klinikum r.d.I., Munich, Germany

We studied the duration of action and permeability of common analgesics and local anesthetics applied dermally via new carriers—transfersomes—in rats and humans. The therapeutic potential of analgesic transfersomes was evaluated in Sprague-Dawley rats subjected to heat and pressure stimuli. Results were compared with those obtained from administration of lidocaine-containing standard liposomes. In rats, subcutaneous injections of 2% lidocaine solution and of liposomal or transfersomal suspension resulted in a strong initial analgesic effect that decayed within 6–7 min. Characteristic withdrawal time is approximately 30 s. Dermally applied analgesic transfersomes, by contrast, increased heat stimulus reaction to >70 s, 130% longer than in controls that received a placebo or a standard aqueous lidocaine solution. In humans, we tested two groups of nine male and female volunteers, aged between 25 and 60 yr, for pain-suppressing activity assessed by the pinprick method. Each subject received a total of 0.5 mL of a transfersomal preparation containing 7% lidocaine or 4% tetracaine over a forearm area of 9 cm. We conclude that the effectiveness of dermally applied anesthetic transfersomes is similar to that of the corresponding subcutaneous injections of similar drug quantities and that optimally designed transfersomes offer a suitable and promising means for the noninvasive treatment of local pain with direct, topical drug application.

(Anesth Analg 1992;75:615–21)

The most popular route for the introduction of analgesics into the body is per os. The effects of oral pain treatment are often relatively diffuse and weak, however. In the case of strong peripheral pain, subcutaneous drug injections are therefore the therapy of choice (1). Analgesic drugs are hardly ever applied percutaneously, owing to the poor therapeutic efficiency of such application resulting from the inadequate penetration of most analgesics through the intact skin.

To date, the development of skin-active analgesic preparations has been based primarily on classical galenic formulations, such as creams or ointments (2–4), which have only a limited transdermal transport potential (5). Only occasionally are more modern drug preparations, such as suspensions of lipid vesicles (liposomes [6]), also used (7). This may be the reason why no analgesic preparation has as yet proved its suitability for dermal application: the resulting analgesia induced by all widely known analgesic formulations is either too weak or sets in too slowly or both. Consequently, even the best current high-potency analgesic formulations for topical use are normally applied under occlusion, the recommended duration of drug application occasionally extending to hours.

We believe that a new type of drug carrier—transfersomes—can circumvent this problem and provide formulations of unprecedented quality for the induction of local anesthesia. We report the first account of such newly developed analgesic transfersomes for the management of local pain in rats and humans. We show that analgesic transfersomes can penetrate rapidly through the intact dermis and can also bring appreciable amounts of analgesic drugs into the skin. Depending on their composition, size, and concentration, the transfersomal drug carriers can reach the cutis as well as the subcutis and, consequently, may affect strongly the physiologic functions of nociceptors and other nerve endings.

With the use of analgesic transfersomes, peripheral pains can thus be suppressed at their very roots.

Methods

Anesthetic Transfersomes

Transfersomes are specially designed, chiefly vesicular, particles. Each transfersome consists of at least one inner aqueous compartment. This is surrounded by a lipid bilayer with specially tailored properties. In the morphologic but not the functional sense, the transfersomes thus resemble lipid vesicles—so-called liposomes. Transfersomes, as used in this study, typically had a diameter of 0.2 μm, with a standard deviation of approximately 30%.

Transfersomes can be made from many synthetic or natural lipids. To ensure optimal biocompatibility, in this study biologic phospholipids from soybean were used as the basic transfersomal component. Specifically, the most common phospholipid, phosphatidylcholine, was chosen and used as a nearly pure (95%+) compound. In addition to phosphatidylcholine, all present transfersomes also contained a small amount of sodium cholate as well as 3%–7% ethanol (puriss). The relative concentration of sodium cholate varied between 50 and 20 mol%, depending on the details of the experiment. This corresponds to a surfactant/lipid weight ratio of between 24% and 10%.

Owing to the amphiphilicity of all standard local anesthetics, such drugs partition preferentially into the interfacial region between the lipid bilayer interior and the aqueous subphase (8–10). They are thus easy to encapsulate. For example, lidocaine can be incorporated into a typical transfersomal preparation nearly quantitatively, provided that the total lipid concentration is sufficiently high. (It is noteworthy that the presence of the drug also modifies the cholate-phospholipid interactions and affects the colloidal stability of the vesicles.)

The investigated transfersome formulations typically contained 2% lidocaine (as a free base) and 4%–8% lipids (wt/vol). This drug/lipid combination is relatively efficient in terms of its therapeutic efficiency in animals and humans. It is colloidally not very stable, however, probably owing to the surfactantlike properties of the encapsulated drug molecules. Further optimization of the detailed composition of analgesic transfersomes for human therapy, therefore, remains to be carried out.

Local Analgesia Assays

To evaluate the therapeutic potential of analgesic transfersomes in animals, we used two test systems. In the "tail-flick" assay, as introduced by D'Amour and Smith (11), a rat's tail was excited by a medium heat stimulus originating from a beam of light (LI 7100 Letica) directed onto the test region. The mean period of time required for a locally anesthetized rat to withdraw its drug-treated tail from the hot spot was then determined. The difference between the results obtained for the transfersome- or saline-treated rats was taken to be a measure of the degree of local analgesia.

The pressure-sensitive nociceptors on the rat's tails were studied by the Eagle and Carlson assay (12) using a Basile analgesimeter. In brief, the threshold value of the mechanical stress needed for the withdrawal of the rat's tail on the induction of pressure was measured. Typically, the weight imposed on a locally treated rat's tail was gradually increased at a constant rate until the test animal spontaneously withdrew its tail. The pressure at which this occurred was registered as a function of the drug-action time and taken to be proportional to the efficacy of the topical analgesia.

For each experiment, a group of 6–10 (most frequently 7–8) Sprague-Dawley rats was used. All animals had a mean body weight of 150 g, were fed ad libitum, had free access to water, and were kept in individual cages before the experiments. All drugs were applied in a volume of 0.1 mL to an area approximately 1 cm long, roughly 1.2 cm from the root of the tail.

To be able to compare different data sets quantitatively and, in particular, to determine the pharmacokinetic system variables, the following phenomenologic expression was used for the experimental data analysis:

$$\text{Anesthesia}(t) = \kappa_1 \exp[(t - t_d)/\tau_1] + \kappa_2 \exp(t/\tau_2), \quad (1)$$

where τ_1 and τ_2 are two characteristic time constants, and t_d is the delay time of the drug action. (Optimal model variable values are given in the legend to Figure 7.)

All results from animal experiments were checked for significance by Student's *t*-test. Values of $P \leq 0.001$, $P \leq 0.01$, and $P \leq 0.05$ were considered significant.

In the studies in humans (who gave informed consent), two groups of nine male and female volunteers, aged between 25 and 60 yr, were tested for the pain-suppressing activity elicited by the dermally applied analgesic transfersomes. Each subject received a total of 0.5 mL of a transfersomal preparation containing 7% lidocaine or 4% tetracaine on one forearm over an area of 9 cm^2 (these concentrations correspond to the upper drug concentration limit in the present formulations that still maintain short-term stability while also being clinically useful).

The application area was kept under occlusion by a

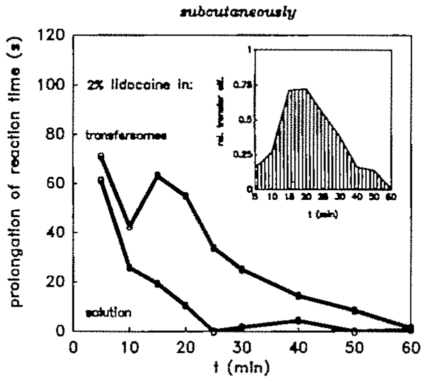

Figure 1. Analgesic action of a subcutaneous injection of 2% lidocaine solution (*lower curve*) or of the corresponding suspensions of liposomes (transfersomes) (*upper curve*), as measured with the rat "tail-flick" assay. The *insert* shows the net effect of drug encapsulation into lipid vesicles. Pain insensitivity resulting from an injection of lidocaine solution lasts only for approximately 10 min; if the same amount of drug is formulated in a liposomal suspension, the resulting analgesia lasts approximately 50 min, reaching 75% of the maximal effect 15–20 min after drug application. All differences but the last differ significantly ($P \leq 0.001$) from the control results. t = time.

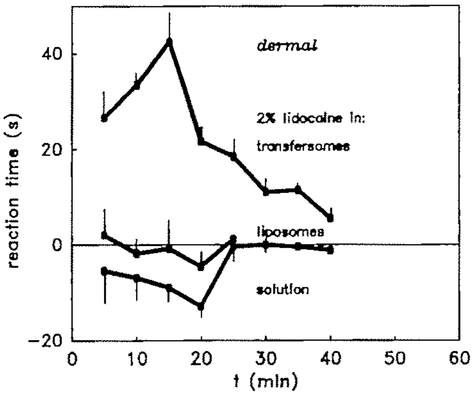

Figure 2. Lag time between induction of a heat stimulus on rat tails and the resulting withdrawal reaction after dermal applications of different analgesic agents. Given values were obtained by subtracting normal reaction times (NaCl treated) from the corresponding drug response data. Animals treated with an aqueous lidocaine solution have a slightly shorter reaction time than animals from the control group treated with 0.9% NaCl. Topically applied analgesic standard liposomes do not reduce the sensitivity of rat tails to pain; conversely, the dermally applied transfersomes induce an appreciable local analgesia within 5 min after application. All results obtained with transfersomes, and no other data points, differ significantly from the controls; $P \leq 0.001$.

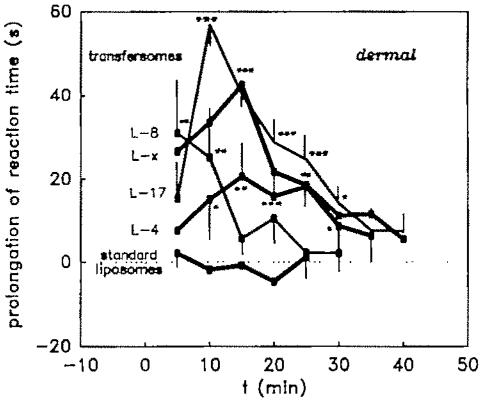

Figure 3. Prolongation of the reaction time to local pain as measured with the "tail-flick" assay with animals given preparations of analgesic transfersomes, liposomes, or analgesic solution directly on the intact skin surface. Lipid concentration was in all cases near 6%. Of all four percutaneously applied analgesic preparations, L-4 [6.6% lipid, 2% lidocaine]; L-x [5% lipid, 4% lidocaine]; L-8 [10% lipid, 2% lidocaine]; L-17 [5% lipid, 2% lidocaine] with similar cholate concentrations (mol%), only the transfersomal formulations containing cholate were capable of decreasing the sensitivity of the rat tails to pain. $^*P \leq 0.05$; $^{**}P \leq 0.01$; $^{***}P \leq 0.001$.

watertight wrapping for 25 min. The wrapping was then removed without further manipulation of the skin surface. Skin sensitivity to local pain was then checked by the pinprick method, as described by Gesztes and Mezei (7) and Lubens (3). For this purpose, 10 pricks covering the whole test area were typically performed at 5, 15, 30, 45, 60, 90, and 120 min after removal of the occlusion. If <6 of 10 pricks were felt by the subject, this was taken to be a manifestation of significant local anesthesia.

Acute Toxicity Assay

The median lethal dose of the lidocaine solution and of lidocaine in transfersomes was determined in Swiss albino mice (20–25 g) by using a standard intraperitoneal assay (13).

Results

Results of animal studies with the analgesic transfersomes are summarized in Figures 1–3. Supplementary data on the induction of local pain suppression are given in Table 1.

Heat Sensitivity

Subcutaneous injection of a 2% lidocaine solution increases the response time of a rat's tail to a heat stimulus from 30 to approximately 90 s, but only for some 25 min. This corresponds to a characteristic decay time of analgesic action of approximately 7 min. The lower curve in Figure 1 shows the representative experimental results.

Subcutaneous injection of a liposomal or transfersomal suspension containing a similar total amount of the anesthetic agent gives rise to a complex, biphasic time-course of local analgesia (Figure 1, upper curve). Soon after injection of the analgesic drug carriers into the rat's tail, the first signs of

Table 1. Effect of Transfersomal Composition on the Therapeutic Efficiency of Dermal Analgesic Preparations

	Reaction time(s)[a]		
	5 min	10 min	15 min
Drug solution	31.5 ± 7.5	31 ± 4.5	25 ± 2.5
Transfersome[b]			
S/L = 1:1	44 ± 1.5	37 ± 1	34 ± 1.5
S/L = 1:2	45.5 ± 5.5	36 ± 1	37 ± 1.5
S/L = 1:4	63.5 ± 5.5	71 ± 3	76.5 ± 6

[a] Reaction time of topically anesthetized rats was measured by tail-flick assay as a function of total sodium cholate (NaChol) concentration in the transfersomal preparations containing soybean phosphatidylcholine (SPC) and 2% lidocaine.

[b] Molar ratio: NaChol/SPC = surfactant (S)/lipid (L).

reduced pain sensitivity appear. This strong initial anesthetic effect decays within 6–7 min. It is thus comparable in its temporal dependence to the analgesia caused by a subcutaneous drug injection.

Ten minutes after subcutaneous application of the analgesic vesicles, the intensity of local analgesia begins to increase again. It then reaches a second maximum 5 min later. The characteristic time constants for the onset and decay of such local pain suppression are approximately 10 and 7 min, respectively, as concluded from data analysis by means of Equation (1). Incorporation of the anesthetic drugs into carrier vesicles thus prolongs the drug effects by some 300%, the decay time of drug activity being nearly unaffected.

Dermal application of the lidocaine solution on the intact skin of rats' tails does not induce noticeable analgesia (lowest curve in Figure 2). This is seen from the fact that four subsequent experimental points all show the same hypersensitivity to pain.

Lidocaine-containing standard liposomes are also very poor dermal analgesics. For a period of at least 25 min after the dermal application of a standard liposome suspension, they cause no significant prolongation of the reaction time to a painful heat stimulus (Figure 2, middle curve). Characteristic withdrawal time of approximately 30 s is nearly identical to that measured in the case of NaCl-"treated" animals.

Dermally applied analgesic transfersomes, on the contrary, can induce analgesia rapidly on their topical application to intact skin. The upper curves in Figures 1 and 2 demonstrate this. Rats that have received a local application of such transfersomal analgesics do not react to a painful heat stimulus for >70 s (not shown). This is 130% longer than in controls that have received a placebo or a standard aqueous lidocaine solution. Net prolongation of the corresponding analgesic effect for a variety of transfersomal populations is shown in Figure 3.

The maximal analgesic effect is induced by a dermally applied suspension of transfersomes some 15 min after the drug application. The characteristic onset and decay times, deduced from the experimental data by means of Equation (1), are then 11 and 6.5 min, respectively. At later times, the pain sensitivity is gradually recovered, and the reaction time decreases again; however, a marked analgesic effect is still noticeable even 30 min after the initial drug application.

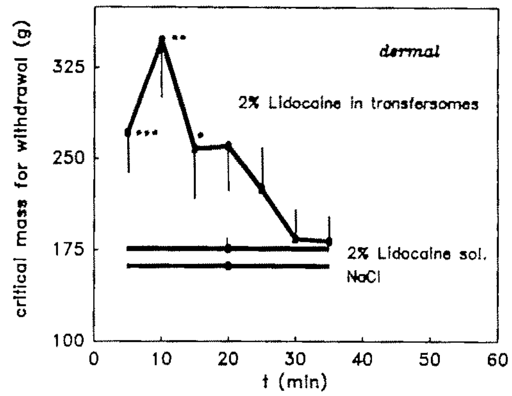

Figure 4. The critical mass that provokes a spontaneous withdrawal of a rat's tail after topical application of various analgesic preparations (Eagle-Carlson test). In contrast to standard lidocaine solutions (sol.), which are analgesically inefficient, the transfersomes containing drugs can decrease the peripheral pressure sensitivity appreciably. $^*P \leq 0.05$; $^{**}P \leq 0.01$; $^{***}P \leq 0.001$.

This shows that the permeation of the analgesic transfersomes through intact skin may cause a delay in the onset of the transferred drug action, although this delay is short. The detailed drug pharmacokinetics thus appears to be determined largely by the intrinsic kinetics of drug action and, in part, by the lidocaine permeation through the transfersomal bilayers. This permeation, as well as the overall drug-transferring efficiency, depends on the carrier composition, as Table 1 illustrates. Table 1 shows that formulations with a very high or very low surfactant concentration are less well suited for induction of local anesthesia than are preparations with an intermediate lipid/surfactant ratio. It should not be forgotten, however, that the overall behavior of a transfersomal drug formulation may also depend on the choice and concentration of the encapsulated drugs.

Pressure Sensitivity

The results of pressure-sensitivity measurements reveal similar trends (Figure 4). Percutaneous treatment of rats' tails with a sodium chloride or 2% lidocaine solution does not result in significant local analgesia. The applied mass that provokes an instantaneous tail-withdrawal reaction in both cases is approximately 175 g. In contrast to this, a percutaneously applied analgesic transfersome suspension increases the corresponding critical mass to approximately 270 g after 5 min and to nearly 350 g after 10 min of drug action. The overall duration of this effect is 30 min, as in the case of the drug-induced reduction of the local heat sensitivity. The corresponding decay times in the former case are somewhat shorter, however.

Induction of Topical Analgesia in Humans

To determine whether our analgesic transfersomes were also active on application to human skin, two groups of volunteers were treated on the intact forearm skin and tested by the pinprick method (3). In this study, only the effects of a single application of drug were tested, which gave rise to a significant but not very persistent local anesthesia. Prolonged pain insensitivity was achieved, however, on repeated drug applications. Clinical applications not reported in this work document this.

Acute Toxicity

The encapsulation of lidocaine in lipid vesicles reduces the overall toxicity of the drug. In our acute toxicity experiments, the 50% lethal doses were found to be 277.3 and 371.0 mg/kg for the free drug and lidocaine combined with lipid vesicles, respectively, the 95% confidence limits being 226.8–339.1 and 301.0–457.3, respectively.

Discussion

Owing to their low molecular weight and high water solubility, most of the standard monomolecular analgesics do not respond to a strong transdermal gradient, nor do they adequately permeate the skin. Thus, analgesics in an aqueous solution, topically applied, do not cross the skin-permeability barrier and thus do not significantly suppress local pain. This is the case before, during, and after evaporation of superficially applied water from the site of application.

Lipophilic analgesics have a somewhat higher chance of achieving the desired therapeutic effect, provided that they are applied under appropriate conditions; however, even with sufficiently lipophilic drugs used in combination with skin fluidizers, the analgesia after a dermal drug application is as a rule rather low.

We have developed a new type of drug carrier that can transport analgesic agents through an intact skin and thus overcome these problems. These carriers are driven by the transdermal hydration gradients (14,15) and were shown to introduce a sufficient amount of analgesic drugs into the cutis and subcutis of a healthy rat tail to cause therapeutically significant relief of local pain after dermal application.

Principle of Operation

In our view, drug carriers must fulfill two basic criteria for a successful transdermal drug delivery effect. If they are to bring an appreciable amount of their payload from the skin surface into the more deeply located skin strata: (a) drug carriers should respond to or create a gradient that drives the drug-carrier complex from the skin surface into the skin interior; and (b) drug vehicles should be able to pass the skin barrier without uncontrollably losing too much of the enclosed therapeutic material.

Transfersomes exhibit good encapsulation as well as a sufficiently potent driving capability to be used as carriers of the water-soluble substances. Transfersome capacity to encapsulate drugs in the present case arises from the fact that the carrier particles used in this study were in the form of a vesicle. Transfersomal drug carriers, consequently, can accommodate anesthetic drugs either in the aqueous interior of a carrier or in the enveloping lipid bilayer for hydrophilic and lipophilic agents, respectively. Carrier penetration is a consequence of the retraction of the transfersomal vesicles from the relatively dry skin surface into the more humid regions of the deeper skin layers (14). All this occurs under the action of the (de)hydration force (16,17). Drug transport in the desired direction is a direct result of this.

Phosphatidylcholine bilayers with added sodium cholate and anesthetic agents appear to be better suited for the purpose of penetration through skin than are pure phosphatidylcholine membranes; this is probably due to their more suitable rheologic and hydration properties. This provides one possible, and plausible, explanation for the observation that only analgesic agents enclosed in suitably optimized transfersomes can reach the subcutaneous tissue spontaneously and with little delay.

We are almost certain, however, that the high drug-carrying potential of the dermally applied transfersomes is not primarily a consequence of stratum corneum fluidization by the cholate molecules. Evidence for this is given in Table 1. If the high therapeutic effect of the analgesic transfersomes was caused by the increased fluidity of the skin lipids, and occurred via the "classical" skin-fluidization route, the degree of therapeutic improvement achieved would have to increase with increasing surfactant/lipid molar ratio. This is not observed, however. On the contrary, the therapeutic effect of the analgesic preparations is relatively low for the micellar carriers with the highest studied surfactant concentration (lipid/surfactant molar ratio 1:1); the drug vehicles with a somewhat lower relative cholate concentration normally perform much better.

It is also unlikely that the therapeutic efficiency of the analgesic transfersomes is due to the fact that

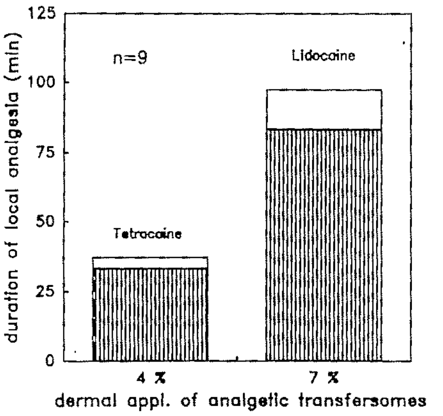

Figure 5. Analgesic effect of two transfersomal preparations with various agents after dermal application (appl.) on human forearms. *Open areas* represent standard deviations.

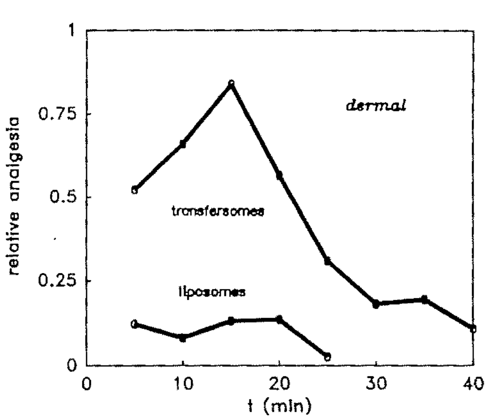

Figure 6. Time dependence of the local, relative analgesia induced by dermally applied lidocaine containing transfersomes or liposomes (normalized net effect). The experimental points were obtained by first subtracting the reaction times measured with lidocaine solution-treated animals from the corresponding data obtained for the transfersome-treated rats and then normalizing the results relative to the longest observed reaction time of 61.2 s. If NaCl-treated animals are taken as a reference, the effect of "analgesic" liposomes is essentially zero (Figure 2).

these carriers have a particlelike appearance. Gesztes and Mezei (7) previously devised a formulation of analgesic "standard liposomes" for dermal applications by using classical galenic recipes. Their preparations thus contained the well-known skin fluidizers propylene, ethyleneglycol, and a fatty acid in combination with the lipid vesicles. The resulting local analgesia after drug application under occlusion was not seen before several hours had passed, however. The absolute efficiency of drug transfer was not reported by Gesztes and Mezei (7) but is likely to have been lower than in our case.

Transfersome-mediated analgesia is not limited to lidocaine molecules as an analgesic agent; this has been confirmed in human studies (Figure 5). It is also not restricted to one type of nociceptor. Different analgesia assays used in this study gave qualitatively similar results. Reduced sensitivity of the topically treated rats to a pressure stimulus (12) resembles closely the corresponding response of similarly treated rats to a heat shock (11) (Figures 3 and 4).

Kinetics of Action

Transfersomal analgesics exert their action more rapidly than other dermal analgesic formulations. In fact, they are nearly as swift in action as an injection needle (Figures 1–4). They are also quantitatively highly efficacious: the integrated effect of percutaneously applied transfersomal analgesics from Figures 1 and 2 can be calculated to exceed 90%.

Consider, for example, the transfersome-induced prolongation of the reaction time in a heat-stimulus assay. To assess this effect, the reaction time of a rat that has been treated locally by receiving a simple lidocaine solution on its tail was subtracted from the reaction time of a rat treated similarly with the appropriate transfersomal analgesic preparation. To clearly distinguish among the relative efficiencies of various therapeutic protocols, all values are here expressed in relation to the corresponding effect elicited by a comparable subcutaneous bolus injection of drug (Figure 1). The latter is assigned a value of 1; in such a representation, the transfersome-mediated local analgesia is obvious.

Liposome-Mediated Prolongation of the Local Anesthetic Action

What about the duration of the transfersome- or liposome-mediated analgesic action? The analgesic effect elicited by subcutaneously applied agents is relatively short-lived. As Figure 1 shows, drug encapsulation into lipid vesicles may improve this by increasing the mean duration of local anesthesia to approximately 0.75 h.

The primary analgesic effect observed immediately after transfersome injection under the skin presumably originates with the nonencapsulated analgesics, which in our case have not been separated from the drug associated with the carrier vesicles. (The fact that the time-course of such first-step analgesia is very similar to the temporal evolution of the analgesia caused by a subcutaneous bolus drug injection corroborates this conclusion.) The prolonged action of the transfersomal analgesics probably results from the gradual drug release from carrier vesicles. Drugs from such carriers reach the skin and the subcutaneous tissues with some delay. Local nociceptors are thus blocked at relatively late times, which gives rise to a more persistent topical analgesia than can be

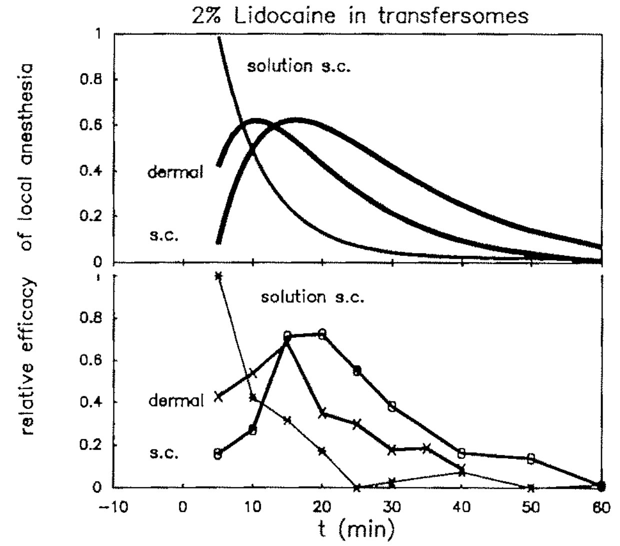

Figure 7. The effective peripheral analgesia caused by percutaneous (dermal) applications of analgesic transfersomes (○), or by subcutaneous (s.c.) injections of lidocaine-containing transfersomes (×); (✻), reference results obtained with lidocaine solution injected under the skin. The *top panel* represents the corresponding model curves, calculated within the framework of biexponential approximation [Equation (1)]. The variable values were t_d = 10.7 min^{-1}; τ_1 = 13 and 6.6 min^{-1}; τ_2 = 10.6 and 10.9 min^{-1}; κ_1 = 11.5 and −3.7; κ_2 = −4.5 and 4, respectively, for dermal and subcutaneous transfersome applications; and τ_1 = 6.7 min^{-1}, τ_2 = 0 min^{-1}, κ_1 = 2, and κ_2 = 0 in the case of subcutaneous lidocaine injections. Optimal carrier vesicles ensure a high degree of topical analgesia that resembles in its overall effect the consequences of a subcutaneous analgesic injection. In the former case, however, the analgesic action sets in with a slight time delay of approximately 10 min, this lag being "therapeutically compensated" in part by the longer duration of the pain insensitivity.

achieved by a subcutaneous drug injection. Of interest, the data from Figures 6 and 7 suggest that the analgesic drug action has a longer duration in the case of a subcutaneous liposome injection than after the dermal application of transfersomal preparations. One possible explanation for this unexpected finding is that the analgesic molecules from subcutaneously injected drug carriers have longer diffusion paths to their target nociceptors than drugs that are applied by means of transfersomes onto the skin surface.

In summary, the antipain effectiveness of dermally applied anesthetic transfersomes has been observed to be similar to that of corresponding subcutaneous injections, provided that similar total drug quantities are used.

Optimally designed transfersomes offer a suitable means for the noninvasive treatment of local pain on direct, topical drug application. By changing the amount and composition of the carriers on the skin surface, the cutis and sometimes even deeper tissues can be desensitized. In humans, complete local anesthesia can be achieved within approximately 30 min by using tetracaine; lidocaine preparations exhibit similar effects after 90 min of dermal action. The resulting local analgesia in both cases lasts for >4 h under suitable conditions (not shown). We believe that this will have far-reaching consequences for the therapy of local pain in humans and animals. It is conceivable that in the future, analgesic transfersomes will be applied safely, routinely, and easily, even by informed patients.

Some questions pertaining to this exciting new type of analgesic therapy remain to be answered, however; for example, the question of the optimal choice of agents and their concentrations, the details of optimal transfersome composition, and the best application mode. Nevertheless, we believe that analgesic transfersomes provide new opportunities in the field of local pain therapy.

Cesarean Section in a Patient With Unilateral Diaphragmatic Paralysis, Brachial Neuritis, and Pregnancy-Induced Hypertension

James A. Faust, Jr., MD, and Norman E. Wilson, MD
Department of Anesthesiology, Maine Medical Center, Portland, Maine

Unilateral diaphragmatic paralysis is usually asymptomatic and rarely requires treatment. When combined with pregnancy-induced changes in pulmonary function, unilateral diaphragmatic paralysis may result in marked respiratory compromise. We present such a case and describe its anesthetic management.

Case Report

A 22-yr-old (gravida 1, para 0) woman with a 36-wk intrauterine pregnancy presented with worsening pregnancy-induced hypertension and increased respiratory distress. Her past medical history was significant for a remote left brachial neuritis and recent mild right brachial neuritis. One month before admission, she noted symptoms of an upper respiratory tract infection that lasted several days. Over the ensuing month, she developed a persistent, nonproductive cough, and increased orthopnea with quick resolution of dyspnea when in the upright position.

Physical examination revealed no breath sounds and dullness to percussion over the right lower lung field, as well as decreased excursion of the right hemidiaphragm on deep inspiration. Chest radiograph showed a 9-cm elevation of the right hemidiaphragm. Spirometry revealed forced vital capacity of 2.24 L (55% predicted), forced expiratory volume in 1 s of 1.91 L (59% predicted), and forced expiratory volume in 1 s divided by vital capacity of 86%. Bronchodilators improved forced expiratory volume in 1 s to 2.3 L (65%). While breathing room air in the supine position, arterial oxygen saturation was 89% and respiratory rate was 30 breaths/min, improving to 98% and 20 breaths/min in the standing position. Postviral unilateral diaphragmatic paralysis was diagnosed, and the patient was treated with inhaled bronchodilators.

One week later, the patient returned with worsening pregnancy-induced hypertension evidenced by a recent 5-kg weight gain to 105.9 kg, arterial blood pressure of 150/100 mm Hg, and peripheral edema. She had a respiratory rate of 30 breaths/min in the supine position. Shortly after admission, she developed right upper quadrant pain, brisk reflexes, and worsening edema. Laboratory results showed increased proteinuria, elevated liver function tests, a platelet count of 220,000/mm^3, and a normal coagulation screen. Intravenous magnesium sulfate was started, and the decision made to deliver the infant. Attempts to induce labor with intravenous pitocin failed, and a cesarean section was scheduled.

In the delivery room, venous access was secured by a 16-gauge peripheral cannula and a central venous pressure catheter. A right radial artery catheter was placed for continuous blood pressure monitoring. Routine monitoring consisted of electrocardiography, pulse oximetry, capnography, and a neuromuscular blockade monitor.

The patient breathed 100% oxygen for 5 min in the supine position, achieving an oxygen saturation of 98%. Anesthesia was induced in rapid sequence with thiopental (250 mg IV) and succinylcholine (100 mg IV) while cricoid pressure was maintained. Arterial desaturation to 65% was noted 45 s after induction. The trachea was intubated, controlled ventilation was initiated, and oxygen saturation quickly increased to 98%. Arterial blood pressure increased from 130/85 to 165/95 mm Hg and was treated successfully with esmolol (50 mg IV), returning blood pressure to 120/70 mm Hg. Anesthesia was maintained with isoflurane (0.5%), nitrous oxide (50%), oxygen (50%), and atracurium (10 mg IV). Oxygen saturation in the supine position remained 97%–98%. A 3.29-kg male, with Apgar scores of 7 at 1 min and 8 at 5 min, was delivered. Cord pH measurement was 7.28. After delivery, anesthesia was supplemented with mor-

phine (10 mg IV). As the incision was stapled, neuromuscular blockade was reversed with neostigmine (3 mg IV) and glycopyrrolate (0.6 mg IV). Anesthetics were discontinued, and the patient was allowed to breathe 100% oxygen. Arterial desaturation to 65% again occurred while the patient was breathing spontaneously in the supine position. The patient was placed in the sitting position, and arterial saturation improved to 99% after 4–5 min of spontaneous respirations. Arterial blood pressure was stable. Respiratory rate was 12 breaths/min, and chest wall excursion appeared both adequate and bilaterally symmetric. The patient's handgrip strength was vigorous and sustained. The trachea was then extubated in the delivery suite without incident.

The patient was observed in the intensive care unit for 24 h postoperatively and then returned to the maternity floor. On the fourth postoperative day, fluoroscopy revealed persistent right hemidiaphragmatic paralysis. The patient was discharged home on the sixth postoperative day with the following oxygen saturations and respiratory rates: 95% and 20 breaths/min in the sitting position, 93% and 24 breaths/min in the left lateral decubitus position, and 92% and 36 breaths/min in the right lateral decubitus position. Three months after delivery, her symptoms were not improved. She had continued dyspnea on minimal exertion and mild orthopnea. Persistent right hemidiaphragmatic paralysis with possible left hemidiaphragmatic involvement was noted. Planned pulmonary evaluation included a sleep study and measurement of transdiaphragmatic pressures.

Discussion

The etiologies of diaphragmatic paralysis include postsurgical (phrenic nerve transection or damage secondary to retraction or electrocautery); neoplastic (direct phrenic nerve invasion or metastatic involvement); neuromuscular (sequelae of myelitis, encephalitis, polio, diphtheria, multiple sclerosis, herpes simplex virus infection); posttraumatic, mechanical (compression from aortic aneurysms or substernal thyroid); infectious (sequelae of bacterial, viral, syphilitic, or tuberculous infection); and miscellaneous causes, including congenital abnormalities, reaction to antitetanus, and idiopathic factors.

Probably most relevant to our patient are the many reported cases that associate diaphragmatic paralysis with brachial neuritis (1–19). Walsh et al. (1) cite cadaver studies from the 1800s showing that in 44% of patients, the diaphragm was partially innervated by the fifth cervical nerve, thereby illustrating an anatomic "link" between the diaphragm and the brachial plexus. They cite further evidence for such a link via the observations of associated movements between the upper arm and diaphragm after aberrant reinnervation following birth injury, trauma, and neuropathy, as well as by notation of such concomitant impairment after avulsion of the fifth cervical root, birthing, and peripheral neuropathies (1).

The anesthetic management of patients with diaphragmatic paralysis begins with preoperative evaluation. When symptomatic, patients with diaphragmatic paralysis most commonly note dyspnea (worse when supine), cough, and chest wall pain. Most patients with unilateral diaphragmatic paralysis are asymptomatic. Clinical diagnosis can be made using a variety of techniques. At the bedside, paradoxical abdominal motion can be observed. Chest radiograph reveals hemidiaphragmatic elevation and is ideally performed with the patient breathing spontaneously in the recumbent position. Fluoroscopic evidence of paradoxical diaphragmatic motion is noted on sniff and cough maneuvers (Kienboeck's sign). Other diagnostic techniques include measurement of transdiaphragmatic pressures, diaphragmatic electromyography, and diaphragmatic evoked responses with phrenic nerve stimulation. Once the diagnosis is made, the etiology of diaphragmatic paralysis may be ascertained from history, physical examination, and chest radiograph alone. If these fail to suggest the etiology, further evaluation is unlikely to elucidate the cause (20).

The choice of general anesthesia for our patient was based on a consideration of the respiratory effects of conduction blockade superimposed on diaphragmatic paralysis. Advantages of regional anesthesia may include reducing the risk of regurgitation and aspiration of gastric contents associated with general anesthesia in pregnant patients at term. Regional anesthesia may avoid a potentially difficult tracheal intubation in the presence of soft tissue edema secondary to pregnancy-induced hypertension. Epidural anesthesia, in particular, may provide more stable arterial blood pressure control and improved uteroplacental blood flow than a rapid-sequence induction of anesthesia in the setting of pregnancy-induced hypertension (21).

However, the major disadvantage of regional anesthesia, in our estimation, was the potential respiratory consequences of high motor blockade superimposed on a term patient already compromised by a paralyzed hemidiaphragm. In adults, the diaphragm is responsible for 30%–60% of tidal volume. Unilateral diaphragmatic paralysis results in decreased total lung capacity, functional residual capacity, forced vital capacity, and tidal volume, with an increase in respiratory rate and no change in the ventilatory response to carbon dioxide. Diaphragmatic paralysis also causes a compensatory increase in inspiratory rib cage expansion secondary to recruitment of accessory inspiratory muscles. Most important, diaphragmatic paralysis results in a new pattern of more rapid contraction of the remaining inspiratory muscles to compensate for the loss of the diaphragmatic component. Whether this new pattern of contraction is vagally mediated is controversial (22–24).

Accessory muscles of inspiration include the external intercostals, scalenes, sternocleidomastoids, alae nasi, and small muscles of the neck and head. Innervation of the intercostal muscles is via the intercostal nerves, which arise from the spinal cord at the same levels (T-1 to T-11). A high motor blockade would therefore compromise the intercostal component of respiratory compensation in the presence of diaphragmatic paralysis. Freund et al. (25) illustrated that a T-4 epidural motor blockade in healthy patients results in an approximately 58% decrease in expiratory reserve volume. In our patient, high epidural motor blockade would therefore further decrease functional residual capacity, making airway closure and the potential for hypoxemia secondary to ventilation/perfusion ratio mismatch more likely.

The strongest argument for choosing general endotracheal anesthesia and controlled ventilation in this setting is illustrated when changes in forced vital capacity in association with conduction blockade are examined. Tracheal intubation and ventilatory support have been recommended at a forced vital capacity of <15 mL/kg for patients with respiratory insufficiency secondary to other motor disorders (26,27). Preoperatively, our patient's forced vital capacity in the upright position was 2.24 L. Clague and Hall (28) showed an average decrease in forced vital capacity of 19% when patients with right hemidiaphragmatic paralysis were placed supine. A change to the supine position would therefore have reduced our patient's forced vital capacity to approximately 1.8 L. Freund et al. (25) illustrated a decrease in inspiratory capacity of 19% with total thoracic motor blockade. Their data with regard to changes in expiratory reserve volume and inspiratory capacity suggest that high thoracic motor blockade would further reduce our patient's forced vital capacity to well below 1.5 L. We therefore chose general anesthesia to ensure adequate ventilation and gas exchange during the procedure.

Our patient experienced marked and rapid arterial desaturation during induction and emergence from general anesthesia. Several factors contributed to the decrease in oxygen saturation. Oxygen consumption normally increases by at least 20% by the end of pregnancy (29). At term, functional residual capacity is decreased by 15%–20% (30), resulting in an increased shunt fraction, and less oxygen reserve. The normal decrease in functional residual capacity at the end of pregnancy is further aggravated by the supine position and the presence of general anesthesia (31). During normal tidal ventilation, one-third to one-half of supine parturients experience airway closure (30). These changes superimposed on the consequences of a paralyzed hemidiaphragm explain the observed arterial desaturation and prompt improvement with the patient sitting at the conclusion of the procedure.

In summary, we report the successful anesthetic management of a patient with hemidiaphragmatic paralysis and pregnancy-induced hypertension undergoing cesarean section. Neither term pregnancy nor unilateral diaphragmatic paralysis alone would have detrimental respiratory implications in most patients, but the combination presents a situation in which the potential for pulmonary decompensation is significant.

We acknowledge Kate Sewall, MD, James Riechel, MD, and Frank Altman, MD, for their editorial comments. We also extend special thanks to Nancy Baker for her help in preparing the manuscript.

Intraosseous Infusion: Elective Use in Pediatric Anesthesia

Frank C. Stewart, MD, and Zeev N. Kain, MD

Department of Anesthesia, Children's Hospital, and Harvard Medical School, Boston, Massachusetts

The intraosseous (IO) route for parenteral access is increasingly being used for resuscitation of infants and children (1). Only one case has been documented in the recent anesthesia literature (2) representing a last resort during cardiopulmonary resuscitation. We report elective use of IO parenteral infusion for induction and maintenance of anesthesia in an infant with no readily available intravenous (IV) access.

Case Report

A 3-mo-old male child was scheduled for revision of a ventriculoperitoneal (VP) shunt. The shunt had been inserted 2 wk earlier but had apparently become disconnected at the reservoir, because cerebrospinal fluid was collecting beneath the scalp, adjacent to the incision.

The patient was a low-birth-weight term infant born at an outlying hospital by normal sinus vaginal delivery after an unremarkable gestational history. Cyanosis and respiratory distress dictated early endotracheal intubation and mechanical ventilation. Echocardiogram and cardiac catheterization revealed multiple cardiac anomalies, including a single left ventricle. Pulmonary artery banding was performed after administration of furosemide and digoxin failed to control progressive cardiac failure. After transfer to our hospital at 18 days of age, he underwent patent ductus arteriosus ligation and removal of the pulmonary band. His prolonged intensive care unit course was complicated by chronic bilateral upper lobe collapse requiring intensive chest physiotherapy, frequent nebulization, and, eventually, bronchoscopy under general anesthesia.

Seizure activity prompted a magnetic resonance imaging scan that revealed large ventricles and cerebral atrophy. The first attempt to place a VP shunt was canceled after several experienced anesthesiologists were unable to establish venous access. The shunt operation was performed the following day after a brachial venous catheter was placed by cutdown, which was the third site attempted that day.

Two weeks later, the patient was scheduled for VP shunt revision after radiographs revealed a disconnection at the cranial reservoir. Because cerebrospinal fluid was extravasating subcutaneously and the patient had a palpably soft fontanelle, he was not thought to have increased intracranial pressure. He received medications and maintenance fluids by nasogastric tube until 2 h before his scheduled operating room time.

A pediatric bone marrow needle was obtained from the emergency department, and a plan was discussed with the surgeons to pursue IO line placement if reasonable attempts at peripheral line placement were unsuccessful. Intraosseous access, including possible complications, was then discussed in detail with the patient's parents.

In the operating room, peripheral IV placement was attempted in all four extremities for 20 min, at which time the decision to use the IO route was made. The needle was placed in the proximal tibia under sterile conditions, requiring 5 min for completion. An intramuscular injection of ketamine and glycopyrrolate had been given before bone marrow puncture, although IO needle insertion can be performed in an awake patient using local anesthetic infiltration. Once access was established, lactated Ringer's solution (10 mL/kg) was administered, followed by pancuronium (0.1 mg/kg) and 5 mL of saline solution flush. Neuromuscular blockade was considered adequate at 180 s by loss-of-twitch response. After intubation, the case proceeded uneventfully, with maintenance fluids and antibiotics delivered by IO route. Reversal of neuromuscular blockade was accomplished through the bone marrow needle, and the trachea was extubated in the operating room. The IO line was maintained in the recovery room for continued delivery of fluids and an additional dose of antibiotics. The line was discontinued soon after the patient's arrival at the ward.

No complications of IO infusion were seen. The child's pulmonary status, although continuing to require vigorous chest physiotherapy and frequent

0003-2999/92/$5.00

nebulization, was unchanged from what it had been preoperatively. The patient was discharged from the hospital 11 days after the VP shunt revision.

Discussion

This case represents an example of an increasing number of infants and children who undergo multiple surgical procedures or long intensive care unit courses and present with impossible IV access. Our patient had occupied an intensive care unit bed for 10 of his 12 wk of life. Central line history included bilateral catheterization of internal and external jugular veins, subclavian veins, and femoral veins. His primary physicians strongly advised against further attempts at percutaneous central venous access because of his complex cardiac anatomy and a history of failure to cannulate the jugular or subclavian vessels. The surgical staff had attempted femoral vein catheterization multiple times on both sides the evening before surgery without success. Multiple cutdowns had previously been carried out on all four extremities, including the femoral veins. A brachial cutdown had been successful 2 wk before this operation but was the third site and required 1.5 h to complete. The number of peripheral venipunctures could conservatively be estimated to number 100–200 over the course of his hospitalization. We believed that IO infusion was the better alternative to a difficult and prolonged venous cutdown in a patient whose polycythemia (hematocrit 56%) would place him at considerable risk if allowed to become hypovolemic.

Intraosseous infusion for the purpose of fluid resuscitation was first described by Doan (3) and Drinker et al. (4) in 1922. Successive reports from the 1930s and 1940s detailed indications, methods, and complications (5–11). The primary indication was for simple fluid resuscitation in infants and young children in whom IV access was difficult. The current use of IO infusions is only a few years old. Its resurgence in popularity filled a clinical need for rapid access to the intravascular system in neonates who would die without immediate infusions of fluid or medications, or both. This rebirth and subsequent reevaluation has been primarily documented in the emergency medicine literature (12–23).

Elective use of IO infusion for induction and maintenance of anesthesia has not been previously reported. Current uses include access during cardiac arrest, shock, extensive burns, and major trauma. Further indications include administration of diazepam and phenytoin for seizure control, continuous administration of dopamine and dobutamine for inotropic support, antibiotics for presumed sepsis, insulin for diabetic ketoacidosis, and administration of a variety of other drugs (16,18,24–28). Use of the IO route has been anecdotally reported for airway management (15,16). Intraosseous succinylcholine can be utilized for airway control in patients with status epilepticus, combative head-injured patients, and pediatric burn patients, and thiopental administration has also been described (15,24). Clinical time to onset of action after IO infusion of several drugs, notably succinylcholine, atropine, and diazepam, has been reported previously (15,16,24). Animal studies have analyzed plasma levels for succinylcholine, atropine, diazepam, and phenobarbital comparing IV, IO, intramuscular, and endotracheal routes (12,17,18). Moore et al. (17) recorded the time to respiratory arrest and loss of forefoot twitch after IV, IO, or endotracheal administration of succinylcholine (1.0 mg/kg) in sheep. Comparing IV with IO infusion, they found that respiratory arrest was delayed by approximately 27 s in the IO group (30.8 ± 7.3 [IV]; 57.5 ± 10.3 [IO]), whereas time to 100% loss of forefoot twitch was slower in the IO group by only 7.5 s (93.3 ± 34.0 [IV]; 100.8 ± 24.2 [IO]). These studies compared favorably with our clinical finding of virtually no delay in relaxation for pancuronium.

The medullary cavity in long bones is composed of a network of venous sinusoids that drain into a central venous canal. Blood exits the venous canal via nutrient or emissary veins into the systemic venous circulation. Children <5 yr old have a highly vascular and primarily cellular marrow; however, after 5 yr, the marrow cavity becomes less vascular and is characterized by more adipose tissue than cellular elements. Fluids delivered via an IO infusion can achieve significant flow rates. Shoor et al. (27), using a 13-gauge needle in a bovine model, obtained flows of 10 and 40 mL/min under gravity and 300 mm Hg of pressure, respectively. Gravity infusion in the infant tibia can typically average >100 mL/h (29). The technique has been reported to be used in the femur, tibia, iliac crest, and sternum. Preferred insertion sites in children include the proximal and distal tibia and the distal femur (1,2,14,23). The proximal tibia is generally agreed to be the optimal site because it has a broad, flat surface covered by a thin layer of skin. However, at ages >5–6 yr, the proximal tibia becomes much thicker and harder to penetrate, making the distal tibia preferable. When using the proximal tibia, the tibial tuberosity is palpated and a point is selected in the midline on the anteromedial, flat surface, 2–3 cm below the tibial tuberosity. The needle is inserted at an angle of 60°–90° away from the epiphyseal plate to avoid any damage. The bevel should point away from the joint space, and a rotary motion is applied, similar to that used for a bone marrow biopsy. Aspiration of bone marrow confirms proper placement.

Use of the IO route for induction and maintenance of anesthesia was suggested in the 1940s–1950s (10); however, this method should not be used routinely in cases of difficult pediatric IV access before considering a number of potential problems. Of the complications associated with IO infusion, extravasation of fluid around the puncture site is the most common. If the extravasated fluid is crystalloid, this presents no problem; however, if it is sodium bicarbonate or some other alkaline agent, local tissue damage may occur. Of more concern is the risk of osteomyelitis and cellulitis. Rosetti et al. (30) reviewed the literature from 1942 to 1977 and found only 27 reported cases of osteomyelitis in >4000 IO infusions. This rate of 0.6% compares favorably with a 3.7% incidence of local infection associated with the use of venous cannulas (31). In addition, the reports of osteomyelitis are from 40 yr ago, before the use of broad-spectrum antibiotics, and involved IO infusions of long duration and of hypertonic solutions. There have been no cases of osteomyelitis reported in the recent literature subsequent to the use of IO infusions. Many physicians are concerned about possible damage to the epiphyseal plate and bone marrow elements. However, there has never been a reported case of damage to the epiphyseal plate, and no lasting negative effects have been identified in multiple clinical and experimental trials (1,14). Potential injury to the growth plate can be avoided by taking care to palpate bony landmarks and to place the needle away from the joint space.

Fat or bone marrow emboli have been regarded as potential complications, but no cases have been documented. Heinild et al. (5), using postmortem examinations of patients, reported no evidence of fat emboli in approximately 1000 pediatric infusions. More recently, Orlowski et al. (26) found a high incidence of fat and bone marrow emboli in the lungs of a canine model subsequent to IO infusion. Ventilation-perfusion relationships, assessed by analyzing arterial blood gases in these animals, failed to reveal any significant change, even though the incidence of bone marrow or fat emboli in pulmonary blood vessels was found to be as high as 4.48 emboli/mm^2. The same authors also reported anecdotally that bone marrow emboli were found in the lungs of two infants who died after major resuscitation episodes, including IO infusions. Whether this data can be applied to humans not undergoing cardiopulmonary resuscitation and not subject to the forces of external cardiac massage is unknown. However, the authors chose to recommend that this technique not be used in patients with intracardiac right-to-left shunts, referring to the theoretically increased morbidity associated with systemic emboli of any type. A recent review article (1) mentioned the possibility of fat embolism but dismissed its importance, pointing out that the marrow of children is relatively fat free. This article did not include children with intracardiac shunts in its list of absolute contraindications (osteogenesis imperfecta, osteopetrosis, and ipsilateral fractured extremity).

For relatively short procedures, IO infusion should be considered by anesthesiologists for cases of extreme difficulty in obtaining IV access in children <5 yr old; however, until further work is done to determine the true incidence of fat and cellular bone marrow embolization, the list of relative contraindications must include the presence of an intracardiac right-to-left shunt and severe pulmonary insufficiency. Although our patient had both of these problems but suffered no detectable complications from IO infusion, we recommend its use only after careful consideration of the risk/benefit ratio in patients like ours.

Seizures and Opisthotonos After Propofol Anesthesia

Curtis B. DeFriez, MD, and Harry C. Wong, MD

Department of Anesthesiology, University of Utah Medical Center, Salt Lake City, Utah

Seizures occurring after general anesthesia are a rare event, and opisthotonos even more rare. Since its introduction in the United Kingdom in June 1986, there have been several reports in the European literature of seizures and opisthotonos occurring after propofol anesthesia. Similar sequelae have yet to be reported in North America. Two cases are described of seizurelike activity associated with opisthotonic posturing that occurred in patients in our ambulatory surgery unit after they received propofol anesthesia.

Case Reports

Patient 1

A healthy 34-yr-old, 85-kg man without a history of alcohol or drug use underwent arthroscopy and menisectomy of his left knee. Anesthetic induction consisted of intravenous midazolam (2 mg) and *d*-tubocurarine (3 mg), followed 3 min later by propofol (2.4 mg/kg). Endotracheal intubation was facilitated by intravenous succinycholine (1.5 mg/kg). Anesthesia was maintained with 70% N_2O in O_2 and propofol infused at 200 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 15 min, then 150 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for an additional 30 min. Intravenous atracurium (20 mg, plus an additional 10 mg) was administered initially to facilitate controlled ventilation. After 40 min, spontaneous respiration was assisted with end-tidal CO_2 measured at 38 mm Hg. Muscle relaxant reversal was not deemed necessary at the end of surgery because the train-of-four ratio was 4/4, and unassisted respiratory effort and gas exchange were normal (end-tidal Pco_2 37–40 mm Hg). Intravenous ketorolac (60 mg) was administered for postoperative pain control, and the propofol infusion was discontinued 15 min before the trachea was extubated. The surgery was complicated by dissection of the isotonic irrigation fluid through the capsule of the knee, with approximately 1 L of lactated Ringer's solution extravasated within the tissues of the upper left thigh.

The vital signs recorded on arrival in the recovery room were blood pressure (126/96 mm Hg), heart rate (68 beats/min), respiration (18 breaths/min), oral temperature (35.6°C), and oxygen saturation (96% on mask oxygen at 8 L/min). Approximately 2 min later, the patient had a generalized, tonic-clonic seizure that was temporarily ablated with intravenous midazolam (5 mg). Within 5 min, a second and then a third seizure, each lasting 1–2 min, were observed. Extension posturing of the head and neck immediately preceded and accompanied each event. The trachea was reintubated after intravenous thiopental (75 mg) and succinylcholine (80 mg). Spontaneous ventilation resumed within 10 min while 50% oxygen was administered through the endotracheal tube. The possibility of hyponatremia or hypoglycemia was excluded by normal electrolyte and serum glucose test results. An arterial blood gas sample drawn just after the first seizure revealed pHa 7.39, $Paco_2$ 40 mm Hg, Pao_2 142 mm Hg, and hemoglobin level 14.3 g/dL. Auscultation of his chest was clear, with no wheezes or rales; he remained hemodynamically stable and well oxygenated for the entire episode. He was admitted to the University Hospital, where head computed tomography scan and electroencephalogram test results were unremarkable. Serum toxicology tests taken just after transport to the hospital showed no evidence of alcohol or illicit drug use. No further seizures were observed, and his sensorium cleared over 4–5 h. The fluid in his left thigh rapidly mobilized, and there was no indication of excessive circulatory volume or electrolyte imbalance. He was observed in the hospital overnight and discharged the next morning.

This patient had been involved in a motor vehicle accident 15 yr earlier and had sustained a closed head injury from which he fully recovered. He denied any personal or family history of a seizure disorder.

Patient 2

An athletic 18-yr-old, 55-kg woman presented for diagnostic arthroscopy of the left knee. Anesthesia

was induced with intravenous midazolam (2 mg) and *d*-tubocurarine (3 mg), followed 3 min later by propofol (2.5 mg/kg) and succinylcholine (1.5 mg/kg) to facilitate endotracheal intubation. The anesthetic maintenance consisted of 70% N_2O in O_2 and propofol infused at 200 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 10 min, then decreased to 120 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 15 min. After endotracheal intubation, atracurium (20 mg IV) was administered to control ventilation, maintaining end-tidal CO_2 at 35 mm Hg. Intravenous ketorolac (60 mg) was administered to help manage postoperative pain. Vital signs and pulse oximetry readings were within normal limits during the operation. At the conclusion of surgery, the neuromuscular block was reversed with edrophonium (25 mg) and atropine (0.5 mg), and a normal ventilatory pattern was confirmed. After an uneventful tracheal extubation, the patient was transported to the recovery room.

The patient's emergence from the anesthesia was unexpectedly delayed, because she remained unconscious for >1 h in the recovery room with normal vital signs and pulse oximetry readings of 98%, with supplemental mask oxygen at 40%. She then awoke and seemed to respond appropriately for approximately 2–3 min, when she abruptly became restless and confused and exhibited pronounced athetoid movements of her head, neck, and limbs. She was given intravenous nalbuphine (10 mg), followed 5 min later by diphenhydramine (25 mg) to ameliorate what was thought to be an extrapyramidal type of dystonia. These drugs served only to temporarily sedate her. Approximately 15 min later, she reawakened more restless than before. Her arterial blood pressure increased to 140/100 mm Hg, and her pupils were widely dilated; but her heart rate and oximetry readings remained stable at 58 beats/min and 99%, respectively. Her agitation and abnormal posturing continued to worsen, progressing to frank opisthotonos with interspersed tonic-clonic seizurelike activity. Her trachea was reintubated after administration of intravenous propofol (90 mg) and succinylcholine (60 mg), and ventilation was assisted with a Jackson-Reese circuit and 100% O_2 during transport to the University Hospital. The patient continued to manifest extension posturing and seizurelike movements, which were temporarily suppressed with three additional bolus doses of propofol (20–30 mg IV) while in the ambulance.

In the emergency room, the opisthotonic posturing became severe, and she was given two intravenous doses of thiopental (75 mg) followed by midazolam (5 mg) by bolus and then by infusion at 4 mg/h overnight, which suppressed all abnormal movements. Head computer tomography scan and spinal fluid analysis were normal. Because of the severity of the opisthotonos, the patient received intravenous midazolam before an electroencephalogram could be obtained. The next morning, after the trachea was extubated, the patient was oriented and cooperative, with no recollection of the postanesthesia events. She developed a postdural puncture headache after a diagnostic spinal tap, which was relieved 2 days later by a lumbar epidural blood patch. She has since returned to normal activities. She has no personal or family history of a seizure disorder and denies any alcohol or illicit drug use.

Neither patient received local anesthetics nor opiates in the operating room, and the second patient was given a single dose of nalbuphine only after the onset of her problems in the recovery room.

Discussion

Seizures occurring during surgery often coincide with the administration of a specific anesthetic, whereas postoperative seizures are more commonly attributable to nonanesthetic causes. This does not seem to be the case with propofol, where the majority of neurologic complications reported to date, other than the minor muscle twitches seen during induction of anesthesia, have developed in the recovery period. Specifically, opisthotonos, previously a rare phenomenon in anesthetic practice, has been a recurrent finding in case reports from the European literature (1–6) and is listed in the packaging insert as a possible adverse reaction. The Committee on Safety of Medicines (the British regulatory body equivalent to the Food and Drug Administration) has received 37 reports of seizures, many accompanied by opisthotonic posturing thought to be due to propofol. Thirteen of these patients are known epileptics, which may represent a population at relative risk. The manufacturer has knowledge of six cases in the United States involving opisthotonos, myoclonia, and seizurelike behaviors that were spontaneously reported to them during the period of November 1989 to the present (personal communication with ICI/Stuart Pharmaceuticals, April 21, 1992). From this information, it appears that the incidence of severe postoperative myoclonic sequalae requiring intervention is very low.

The mechanism by which propofol may act to produce these neurologic events is unclear. As pointed out by Modica et al. (7) in their recent review of the pro- and anticonvulsant effects of anesthetics, what we observe clinically as a "seizure" may or may not represent the high-voltage electrical discharge characteristic of true cortical seizures. Without electroencephalographic monitoring, they conclude, "it is extremely difficult to determine whether abnormal appearing seizure-like muscle movements are due to epileptiform activity or nonepileptic myoclonia." Opisthotonos, for instance, is rarely seen with cortical epilepsy but is a form of acute dystonic reaction that may be seen after administration of phenothiazine-type drugs acting at subcortical sites. Indeed, there is some evidence in a mouse model that propofol exerts effects at these deeper structures (8). Yet, Hodkinson et al. (9) reported three patients undergoing electrocorticographic mapping of seizure foci who developed true cortical epilepsy after a bolus dose of propofol (2 mg/kg). In each instance, they observed complexes consisting of spikes, polyspikes, and spike and slow waves commencing 20–30 s after injection and persisting for up to 7 min. In contrast to these data, Lowson et al. (10) studied the protective effects of propofol against electrically and chemically induced seizures in mice and concluded that propofol possesses strong anticonvulsant properties. Propofol also diminishes seizure duration during electroconvulsive therapy in humans (11,12). Like other drugs that manifest both pro- and anticonvulsant activity, such as barbiturates, ketamine, enflurane, and etomidate, propofol has been used successfully to ablate status epilepticus refractory to other therapy (13,14).

Although the dose of propofol used in our two patients tends toward the upper limit usually used in clinical practice, a review of the published literature fails to demonstrate a specific dose-response relationship to the events we are reporting. Although most of these patients, including the two discussed in this report, displayed only brief episodes of postanesthetic abnormalities, there have been reports of prolonged difficulties that cannot be directly related to the short hypnotic action or rapid elimination from blood of propofol. Hopkins (4) documents a case of a 29-yr-old woman who received 150 mg of propofol (2.5 mg/kg) and suffered apneic attacks, recurrent seizures, and opisthotonos for 23 days postoperatively. Another woman from Denmark reportedly had seizures for 7 days after propofol anesthesia despite antiepileptic medications (15).

This leads some to speculate that a metabolite may be at fault. To our knowledge, none of the known metabolic by-products (several propofol glucuronides and the 4-sulfate conjugates of 1,4-quinol) are epileptogenic.

We report these two cases to raise the awareness of anesthesiologists to the possibility of seizurelike activity and opisthotonos associated with the use of propofol in combination with many anesthetic techniques. Many anesthetic and analgesic drugs are known to produce seizure activity clinically, but the emergence of opisthotonos, and a variety of other athetoid behaviors in the postoperative period, is almost uniquely associated with the use of propofol. The adjuvant drugs used during anesthesia were administered in small quantities, whereas the propofol was infused at rather high doses. We noted a striking exacerbation of symptoms in our second patient after administration of repeated boluses of propofol during the recovery period. Also, propofol is implicated in a number of similar reports from Europe, where it has been in clinical use since 1986. Although clinical evaluation of these two patients does not conclusively demonstrate the administration of propofol to have caused the neurologic aberrations we report, we could not find other likely explanations. Unfortunately, the current paucity of information with regard to these phenomena and how they may relate to different dosages and methods of administration of propofol, as well as differences in patient populations, makes it difficult to draw definitive conclusions or make treatment recommendations.

Letters to the Editor

Sympathetic Dystrophy: New Name, New Concepts, New Treatment?

To the Editor:

We have read with interest the preliminary results by Vanos et al. (1) about the use of ketorolac in patients with sympathetic maintained pain (formerly sympathetic reflex dystrophy). We agree that it is compulsory to perform prospective, controlled and double-blind studies before accepting this new treatment. An excessive production or response of some prostaglandins in this type of pain is supported by more scientific data. Perhaps prostaglandin-induced hyperalgesia is mediated by a presynaptic (postganglionic sympathetic neurons) release of prostaglandins stimulated by norepinephrine (2,3). Taiwo et al. (4) reported the direct effect of cyclic adenosine monophosphate as second messenger in peripheral hyperalgesia in primary afferent nociceptors. Also they suggested that it could be the final common pathway for many agonists in nociception, including the direct acting prostaglandin E_2. In another publication, the same authors (5) demonstrated the blocking effect of morphine (by stimulation of μ-receptor in the primary afferents) on prostaglandin E_2's induced hyperalgesia, but not on the intracellular effects of 8-bromo cyclic adenosine monophosphate (a cell membrane diffusible cyclic adenosine monophosphate analogue). Kimbal (6) has described a new scheme to understand the interaction of physiologic products in neurogenic inflammation that binds prostaglandin E_2, interleukin (IL), histamine, bradykinin, and others, all linked to substance P. Regarding sympathetic maintained pain, IL-8 could have a direct pain generating role successfully blocked by antiadrenergic drugs, but not by the cyclooxygenase inhibitor. Cunha et al. (7) proposed that IL-8 could be an intermediator between tissue damage and sensitization of pain receptors, leading to the development of sympathetic hyperalgesia.

Recently, Drummond et al. (8) challenged the classical conceptions of sympathetic maintained pain as being an increase of sympathetic outflow in the diseased limb. Instead they observed a decrease of 3,4-dihydroxyphenylethyleneglycol and catecholamines in venous samples of affected limbs in patients diagnosed with sympathetic maintained pain, therefore, probably finding a decrease in sympathetic outflow!

If sympathetic control is still the probable main factor in the physiopathology of sympathetic maintained pain, several other mediators (as suggested above) could also be involved. That could explain the usefulness of treatments different than sympathetic blockade.

Wet Tap Due to Epidural Needle Defect

To the Editor:

Most anesthesiologists use the loss of resistance technique to locate the appropriate endpoint when placing an epidural catheter. Soft interspinous ligaments or a leak at the Luer lock between the syringe and needle may cause a decrease in resistance below the expected amount. This case demonstrates another cause of decreased resistance and reminds us to inspect and test the whole syringe-needle unit for integrity before starting the procedure.

Recently, on our chronic pain service, we evaluated a 47-yr-old woman with syringomyelia and a spinal cord injury resulting from a complication during biopsy of her thoracic syrinx. She presented with severe right-sided pain refractory to all employed modes of therapy and was to undergo a trial of continuous epidural narcotic therapy. For the epidural placement, the patient was placed in the sitting fetal position with her feet on a chair, and with head down on her bedtable to provide maximum thoracic kyphosis. After betadine preparation and 1% lidocaine infiltration

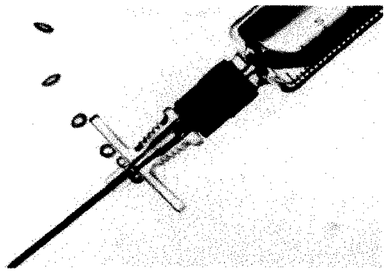

Figure 1. Underwater leak test shows rising air bubbles from the defective junction of the metal and plastic parts of the epidural needle.

of the skin and subcutaneous tissue at the T7-8 interspace, a 17-gauge Tuohy needle (Arrow Inc.) was placed easily into the interspinous ligament. Using the loss of resistance technique with a 3-mL volume of air in a 5-mL lubricated glass syringe, the needle was carefully advanced. During needle advancement, an unusually low resistance was felt in the plunger. The syringe-needle connection was confirmed secure. The first two attempts at finding the epidural space were unsuccessful and were without complication. On the third attempt, the same unusually low resistance was encountered, and despite efforts to the contrary, the dura was punctured and significant wet tap obtained. The needle was quickly removed. At this point, a new epidural needle was used, a new interspace chosen, and the needle was easily placed in the epidural space without complication. The epidural narcotic trial went well but the patient suffered a severe postdural puncture headache.

Immediately after the original needle was removed from the patient, the attending anesthesiologist examined it and placed it in a water bath, where under positive pressure, an air leak was noticed at the junction of the plastic hub and metal needle shaft. This is shown in Figure 1. The defect was large enough to cause the change in ligament resistance we observed.

In view of our experience, it may be worthwhile to check the needle-syringe combination for such defects before using the needle by occluding the needle tip with a sterile gloved finger and applying pressure to the syringe plunger.

A review of the literature did not reveal any previous reports of this complication.

Tongue Numbness as the Early Sign of 2% Lidocaine Intravenous Epidural Catheter Migration

To the Editor:

The interesting case report by McLean et al. (1) of intravascular migration of an epidural catheter despite multiple test doses and techniques emphasizes the importance of early clinical observation of intravenous injection of lidocaine.

Four years ago, we described a case in which tinnitus was the early diagnostic sign of intravenous injection of 0.5% bupivacaine (2). We now report a case in which tongue numbness expressed itself as the early sign of 2% lidocaine intravenous injection through an epidural catheter.

A 30-yr-old parturient in her second gestation was brought to the operating room for cesarean section because of no progress of labor. Three years earlier, she had had epidural analgesia for delivery of twins. However, because of difficulty with delivery of the second newborn, she was rushed to the operating room, where the second newborn was delivered via cesarean section under general anesthesia. She then required 8 U of blood because of disseminated intravascular coagulation.

On the present occasion, an epidural catheter was inserted through the L3–4 interspace while another spinal injection was performed at L2–3 with 1.5 mL of 0.5% bupivacaine. However, there was no indication of spinal anesthesia 15 min later despite cerebrospinal fluid that had been flowing through the 25-gauge spinal needle before the anesthetic was injected. Then, 5 mL of 2% lidocaine was injected through the epidural catheter. Five minutes later, the patient complained of dizziness and tingling in her tongue. This sensation passed after another 5 min. Then, another 4 mL of 2% lidocaine was again injected through the epidural catheter, which elicited the same sensation of dizziness and tongue numbness. There were no signs of seizures or difficulty in breathing. Intravenous migration of the epidural catheter was determined to be the cause; the patient's trachea was then intubated and cesarean section performed under general anesthesia. Blood at the epidural catheter orifice was found after its removal at the end of the operation.

McLean et al. (1) stated that there was no change in mental status until the occurrence of the grand-mal seizure after the administration of 18 mL of 2% lidocaine with 1:200,000 epinephrine and 100 mg of fentanyl. Perhaps the addition of fentanyl or epinephrine obscured the early signs of lidocaine toxicity.

I propose the use of 2% lidocaine alone as a test dose through the epidural catheter and the search for tongue numbness as the early clinical sign of intravenous 2% lidocaine injection through a migrated epidural catheter.

Two Cheers for Anesthesiology Journals, 1992: A Reply to Greene

To the Editor:

Greene's perceptive article (1) about anesthesiology journals, like Keats' earlier one about monitoring (2), is an example of the true purpose of academia: to challenge perceived wisdom (3). He is not the first to question where our sagging anesthesia library shelves are leading us; Duncan and Cohen (4) concluded that "the literature has become too confined in scope and reductive in reasoning."

Greene's analysis was somewhat incomplete in ignoring the reasons for the increase in publications. Certainly, as he suggests, the publishing houses are partly responsible, but they are only supporting a need—the need for anesthesiologists to prove themselves by publishing papers or, for that matter, by serving as editors or on editorial boards. It is part of the wider academic culture that encourages spurious publication to obtain grants and promotions rather than to communicate with others (5); and so long as pharmaceutical companies provide easy funding for clinicians to test their products, we are unlikely to reduce the number of pages devoted to trivia, the second form of what Greene aptly describes as "space-occupying lesions."

Anesthesiology is not alone in these difficulties; the whole of clinical medicine, even the whole of science, seems in danger of drowning in a sea of irrelevant and ever more reductionist information. Greene asks us not to "hide within a sub-subspecialty," but this is also happening to the rest of science. In 1990, the *Lancet* received more than 100 new journals (6). In this week's (April 2, 1992) issue of *Nature*, there are advertisements for these new journals: *Nature Genetics, Human Molecular Genetics, Molecular Phylogenetics and Evolution, Biological Signals,* and *Cellular Physiology and Biochemistry*. Sommer (7), reviewing *DNA Sequence: The Journal of DNA Sequencing and Mapping,* wrote, ". . . I anticipate it will soon spawn a companion journal, *RNA Sequence,* which in turn will spawn *Codon* and *Untranslated Regions*. Such is the nature of progress." That issue of *Nature* (October 3, 1991) included advertisements for *Quality of Life Research, Minimally Invasive Therapy, Gynaecological Endoscopy, Neurodegeneration,* and *The Breast,* selected from many others as at least being directly relevant to clinical medicine.

A specialty that has to remain as generalist as anesthesia is bound to suffer from these superspecializations. It will suffer in the clinical sphere, as clinicians peeling off their ever more specific disease interests come to regard the generalists as amateurs, and in the scientific sphere, as the present equating of grant money with measurement of research success downgrades everyone unable to get a piece of the action in "big science."

Nevertheless, I agree with Greene: we must be courageous and remain generalists. One day our time may come; reductionism is fashionable but has no sole rights to truth. It is worth remembering that public health medicine has saved more lives than DNA manipulation is ever likely to do.

What disappoints are Greene's defeatist solutions, which amount to little more than resigned capitulation. The present state of reviewing is anarchic and self-gratifying; there is a "growing army of review writers" (8), and a "large proportion of the research community must be writing, or have recently written, a review" (9). Review and meta-analysis (10) are important and are, I believe, the only way for busy clinicians to make sense of research findings. Reviewing must be as scientific as the original research is supposed to be, and there must be funding (11) to enable qualified people to review and analyze as part of their recognized work instead of yet another extra that they do, often for paltry commissions.

Greene's suggestion that we shall all simply have to resign ourselves to more reading is unacceptable. We do not have the time. Greene's figures for number of issues of anesthesiology journals by decade fits the exponential equation $y = 6.36 \times 10^{0.017x}$ (where y is number of issues, x is year, and 1922 is taken as year 1); the correlation coefficient is 0.996. (Of note, the exponent is nearly the same as for growth in the total number of biomedical journals [12].) If this rate of growth continues, the resident of today, who has 98 issues to read each year, will have 224 to read in the year 2012 and 332 to read as retirement approaches in the year 2022. That is without the intensive care journals, pain journals, general medical journals, general scientific journals, journals of other interests (I subscribe to the *Journal of Medical Ethics*), newspapers, and news magazines—these last of importance because we are a part of the community in which we care, as Greene humanely put it, "for the entire patient, not just part of him or her."

Medical knowledge is expanding faster than anyone can keep up with, but we are perhaps deluding ourselves by pretending that it is so very important. In parts of Africa the mortality rate in the first year of life is more than 150 per 1000 live births. If people's lives are really to improve, they need better social conditions.

Some, including the editor of *Nature* (13), think that the new technology will be an influence for sanity in scientific publication, but I withhold judgment; publication could just as easily become more unmanageable and even less controllable (or definable?), even if more readily accessible. We may not succeed, but anesthesiologists and other generalists have an important part to play in keeping medical feet on the ground. We are less able to do that if we have less time to lift our heads and look around us. We cannot directly control publication, but we can examine critically the driving forces and ask whether they cannot be curbed.

Faced with more journals and more issues of those journals, the only sensible solution is to be more selective in what we read. The most important of Greene's five ways of change was the second: to learn and teach the skill of interpreting what is written and to select sensibly what to read.

Anesthesiologist's Interactions With Other Medical Departments Outside the Operating Room

To the Editor:

We read with interest the article by Cheng et al. (1). Their survey has formally called to our attention a problem that affects many institutions and, to a great extent, directors of departments of anesthesia. As the representative of the American Society of Anesthesiologists to the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) Hospital Professional and Technical Advisory Committee (B.S.E.), and as Vice President for Research and Standards, JCAHO (P.M.S.), we have been confronted with questions about the issues addressed by Cheng et al. and believe that some of their statements and interpretations need clarification.

On page 274, second paragraph, they state that, "the director of anesthesia services is responsible for *developing* [italicized for emphasis] approaches to effectively monitor and evaluate the quality and appropriateness of anesthesia care provided by individuals in any department/service in the hospital, including but not necessarily limited to, the ambulatory care, dental, etc., ..." Later, on the same page, they state that, "we believe this should not be used as an excuse to avoid *participating* [italicized for emphasis] in the evaluation of the quality and appropriateness of the use of anesthetic drugs outside the operating room." Further, on page 275, they state that, "as the JCAHO is advocating the active participation of anesthesiologists in monitoring and evaluating anesthetic care in hospital departments outside the operating room, neglecting this responsibility may put the anesthesiologist at risk for litigation problems in the future."

JCAHO standards do *not* require that the director of the organized anesthesia department/service *develop* "approaches to effectively monitor and evaluate . . . etc.," but rather that he or she *participate* in their development. The director is not required to assume responsibility for administration of anesthesia for those over whom he or she has no authority. To clarify the entire issue, the Intent of the standards has been published (2) in the Scoring Guidelines of the 1992 *Accreditation Manual for Hospitals*, Volume II, Surgical and Anesthesia Services chapter, page 7. The following is the exact wording of the scoring guidelines:

> INTENT The director of the organized anesthesia department/service, or a designee(s), directly participates with individuals from all other departments/services in which anesthesia services are provided in the development of mechanisms or processes
>
> - to provide services that are consistent with patient needs and current practice,
> - for monitoring and evaluating anesthesia services, and
> - for establishing guidelines for the safe administration of anesthesia.
>
> These standards do not prevent other directors from assuming responsibility for anesthesia services provided in their department/service. If the director of organized anesthesia service objects to a policy established by an individual department/service director and the disagreement cannot be resolved, it should be brought to the medical staff for resolution through appropriate established channels (for example, the medical staff executive committee).
>
> The director of each department/service in which anesthesia services are provided is responsible for the monitoring and evaluation of the quality of patient care provided in the department/service, consistent with current knowledge of anesthesia practice. The director of the organized anesthesia department/service facilitates and provides consultation on the monitoring and evaluation of the quality of anesthesia services provided in hospital departments/services.

In Response:

Anesthesiologist's interactions with medical departments outside the operating room are often limited. The intent of our survey and analysis (1) is to call the attention of anesthesiologists to the frequent use of anesthetic drugs by nonanesthesiologists and to point out that as a specialty, we can be an important resource for other medical departments utilizing anesthetic drugs.

We thank Drs. Epstein and Schyve for their interest and comments. We agree that the directors of each department are ultimately responsible for the quality of patient care in their own departments; however, we should not avoid our responsibility in helping with the monitoring and evaluation of the quality of anesthesia outside the realm of our direct control.

Who should know better the use of anesthetic drugs and safety concerns of administering an anesthetic than an anesthesiologist?

Preemptive Analgesia: An Early Observation

To the Editor:

Ejlersen et al. (1) in a well-designed study have added another valuable piece of information in the evolving field of preemptive analgesia. They did not, however, cite a reference that deserves to be credited as one of the earliest scientific observations in this area. Neill (2) reported in 1978 reduced need for postoperative analgesia in patients after regional anesthesia, compared with the same patients after general anesthesia. Despite this report, interest seems to have remained dormant until the major advances in pain mechanisms of the early 1980s.

In Response:

We are grateful to Dr. Bourke for drawing our attention to the report by Neill (1), which unfortunately escaped our attention. However, the study by Neill did not address the key question in our paper: whether preincisional infiltration of the surgical wound is more effective in preventing postoperative pain than postincisional infiltration. Rather, Dr. Neill only showed that preincisional plexus block with bupivacaine before general anesthesia significantly increased the time to administration of the first postoperative analgesic compared with general anesthesia alone.

Colorimetric Carbon Dioxide Detection

To the Editor:

The recent article by Sum Ping et al. (1) reiterates the concern that diagnosis of esophageal intubation using capnography or colorimetric detection may be difficult if CO_2 is present in the stomach (2,3). Their conclusions, however, that the FEF CO_2 detector (now Easy Cap, Nellcor) is not suitable for determining correct placement of the endotracheal tube are not well supported by their data nor those of other investigators. We contend that the article has certain study design features that significantly limit the application of their data to the clinical situation, and, further, we would like to cite several studies that appear to contradict to some degree their results. Readers might be encouraged to peruse the reports of O'Flaherty and Adams (4), Goldberg et al. (5), and Varon et al. (6), which collectively represent 222 patients in which use of the FEF (now Easy Cap) detector was shown to be highly effective.

With regard to the study design in the article by Sum Ping et al. (1), the swine (unknown weights) had 150 mL of carbonated beverage instilled into their stomachs, followed by six normal tidal breaths via an endotracheal tube placed in the esophagus and then had the CO_2 detector connected to the esophagal tube. It appears that no time was allowed to elapse between the instillation of the beverage and the evaluation of the CO_2 detector other than the six breaths. The chances of a rapid engulfment of this volume of carbonated beverage occurring within seconds or even 1 or 2 min before intubation is not likely. Further, the volume of beverage may have been in excess of normal human intake, depending on the weight of the swine. A more appropriate study design would have incorporated timed evaluations of the CO_2 detector for periods up to 1 h after instillation of the beverage. In fact, Heller et al. (7) conducted studies evaluating the same detector in swine 5–10 min after beverage instillation and with cardiorespiratory arrest. They found that after 5 min, carbonated beverages did not result in false color changes in the colorimetric detector. In similar studies evaluating capnography with esophageal intubation after carbonated beverage ingestion in dogs, Garnett et al. (2) found that 40% had no esophageal capnographic record after 10 min and that 60% had average peak CO_2 concentrations of 5.18% ± 2.61%, decreasing to <1% after eight breaths, and in those animals monitored for 20–30 min, the CO_2 concentrations were approximately 0.2% after six breaths. These low levels of CO_2 (~0.2%) did not cause Heller et al. (7) any difficulty with use of the disposable colorimetric detector.

In Response:

The concerns put forward by Drs. Butler, Leiman, and Katz were (a) limited application of our data owing to the design of our study; and (b) contradiction between our results and those of other studies. Our response follows.

In our study (1), esophageal ventilation was performed soon after the administration of carbonated beverage. We believe that the CO_2 level would have been higher had we waited 10 min, because the time for the CO_2 level to reach a maximum after the instillation of carbonated beverage into the stomach is 10 min, as shown in our previous report (2). This probably explains why Garnett et al. (3) observed a CO_2 level >8% (our highest CO_2 level was only 5.3%) during esophageal ventilation 10 min after the instillation of carbonated beverage. Garnett et al. (3) did not wait 20 and 30 min before performing esophageal ventilation, as implied by Dr. Butler and colleagues. They repeated esophageal ventilation in the same animals at 20 and 30 min without further instillation of carbonated beverage, and the CO_2 levels obtained were predictably lower at 0.90% ± 0.22% and 0.60% ± 0.08%, respectively. We believe that the CO_2 levels would have been higher had the esophageal ventilation been performed for the first time at 20 or 30 min. The real question here should be, how does time affect CO_2 concentration in the stomach after instillation of carbonated beverage? The CO_2 concentration depends on the rate of production and excretion. The CO_2 is released into the stomach from the carbonic acid in the beverage whenever CO_2 concentration in the stomach decreases below that of the carbonic acid until exhaustion of the latter. Excretion of CO_2 from the stomach is by passive absorption through the mucosa into the blood circulating in the capillaries of the stomach until CO_2 concentration in the stomach decreases to the level present in the blood. A larger volume of carbonated beverage ingested will maintain a high CO_2 concentration for a longer duration. In our study, 150 mL of carbonated beverage at 2°C was administered to Yorkshire swine weighing 35–40 kg. How long a can (355 mL) of carbonated beverage will maintain a high CO_2 level in the stomach of a 70-kg person cannot be extrapolated from our study. We wanted to show that high CO_2 level can be obtained during esophageal ventilation in the presence of carbonated beverage in the stomach, a finding that conforms to the results obtained by Garnett et al. (3) and Zbinden and Schüpfen (4).

Heller et al. (5) did not observe any color change in the FEF CO_2 detector (now Easy Cap, Nellcor) during esophageal ventilation in any animal after the instillation of carbonated beverage into the stomach, whereas in our study, there was no color change and no CO_2 obtained only in one of six swine. In the Heller et al. study, two of the four animals died during esophageal ventilation, and CO_2 level was not measured quantitatively. It would be difficult to determine whether the absence of color change was real or subjective. In a previous study (2), we showed that the color-matching process with the FEF CO_2 detector was not always easy, and there was a variation in the color chosen by the different blinded observers, even when the volume and CO_2 concentration of the gas mixture injected through the detector were the same. During cardiopulmonary resuscitation (CPR) of the remaining two animals, the FEF CO_2 detector was not used to monitor tracheal ventilation. The color change corresponding to low CO_2 level obtained with tracheal ventilation during CPR can easily be confused with the color change in the FEF CO_2 detector during esophageal ventilation.

Our results did not contradict those of O'Flaherty and Adams (6) and Goldberg et al. (7), although our conclusions differ. They both conclude that the FEF CO_2 detector is safe and reliable on the basis of successfully identifying esophageal intubation in 19 and 11 instances, respectively. All patients in both studies had normal hemodynamics. When the hemodynamic is compromised, as during CPR, the FEF CO_2 detector is no longer reliable in assessing correct placement of the endotracheal tube, especially in the presence of carbonated beverage in the stomach. Small or no color change in the FEF CO_2 detector can occur with both esophageal and tracheal ventilation during CPR. Contrary to what Dr. Butler and colleagues mentioned, Varon et al. (8) found the FEF CO_2 detector to be reliable in identifying esophageal intubation only after emergency intubation for respiratory distress and not during CPR, a conclusion that concurred with our belief.

We would like to point out a very important principle in the assessment of various monitors. Whether a monitor is assessed as good or bad depends on the criteria one demands of the monitor under the conditions it will be used. The capacity to identify placement of the endotracheal tube rapidly and accurately is paramount under any circumstance, including CPR. If, for example, a monitor has a 95% success rate, one would normally tend to assess the monitor as good; but if that monitor is used as the sole means of correctly assessing position of the endotracheal tube when the vocal cords are not visible and a capnographic monitor is not available, is it good enough?

Respiratory Obstruction in the Recovery Room

To the Editor:

We wish to describe a case that has not previously been described in the medical literature. The patient was a young, healthy woman who underwent an uneventful vaginal hysterectomy. At the conclusion of the procedure, the patient was transported to the postanesthesia care unit while breathing supplemental oxygen spontaneously via an endotracheal tube. On arrival, she was placed on 100% oxygen mist via T-piece and connected to routine monitors. Shortly after arrival, the patient's face was noted to be flushed, and oxygen saturation decreased to the low 90% range. Physical examination revealed minimal breath sounds, bilateral jugular venous distention, and erythema of the neck and face. No mist was observed to be coming from the expiratory limb of the T-piece. She was rapidly disconnected from the T-piece and breathed from the transport oxygen. Her oxygen saturation immediately increased, and auscultation revealed decreased bilateral breath sounds. A chest radiograph revealed bilateral pneumothoraces that necessitated bilateral chest tube placement. Subcutaneous crepitus was noted from her sternum to her orbits. The chest tubes were removed 3 days later, and the subcutaneous emphysema resolved without complication. Inspection of the T-piece revealed that the plastic wrap had been stretched over one open end of the T-piece, which produced complete obstruction when the expiratory limb was added. The fresh gas flow of 15 L/min increased intrathoracic pressure, impeded venous return, and caused the bilateral pneumothoraces and subcutaneous emphysema.

We propose that to reduce the risk of this recurring, (a) practitioners be aware of the possibility and include it in the differential; (b) respiratory therapists be trained to completely unwrap the T-piece before assembly; and (c) practitioners listen to the chest after connecting any respiratory therapy device and note the presence of expired mist in the expiratory limb.

A Preliminary Study of the Ultrasound Examination of the Vocal Cords and Larynx

To the Editor:

A noninvasive method for visualizing the vocal cords and larynx would be a useful tool in the management of difficult intubations and as an aid to the diagnosis of vocal cord abnormalities. Therefore, we tested the capability of ultrasound imaging of laryngeal structures to guide endotracheal intubation and to diagnose vocal cord abnormalities noninvasively. Twenty healthy adult volunteers and 10 full-term newborn infants without apparent laryngeal pathology were successfully scanned. As shown in Figure 1, the false vocal cords appeared as paired hypoechoic structures, and the true vocal cords appeared as paired hyperechoic structures. The symmetric abduction/adduction of both the true and false vocal cords was easily observed. Ten adult patients undergoing direct laryngoscopy to evaluate suspected vocal cord lesions were also scanned. In each case, ultrasound scanning demonstrated the presence of vocal cord paralysis seen on direct laryngoscopic examination. Next, the real-time ultrasound image of the vocal cords and larynx was successfully used to guide the endotracheal intubation of an awake, healthy volunteer (Figure 2). However, additional attempts using ultrasound-guided endotracheal intubation in 10 anesthetized patients proved unsuccessful in 8 as a result of difficulty in adequately visualizing the tip of the advancing endotracheal tube. The use of a stylet, foam cuff, or Doppler implanted endotracheal tube did not increase endotracheal tube visualization. The present study demonstrates that high-resolution ultrasonography is capable of producing good quality images of the vocal cords and larynx. Further

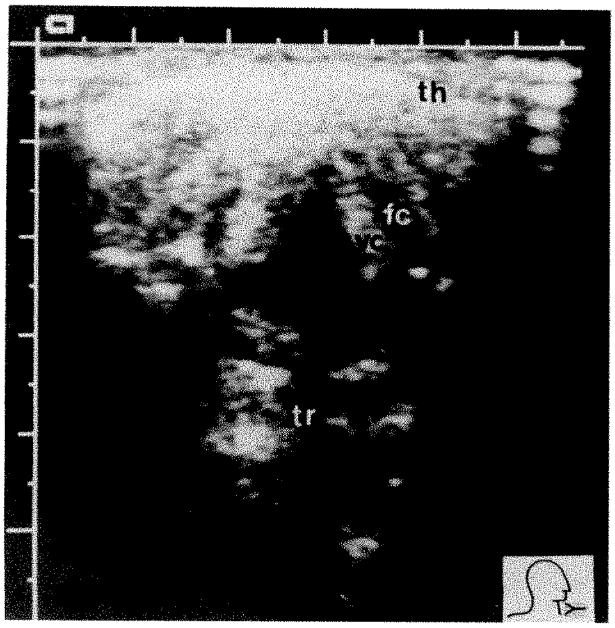

Figure 1. Laryngeal (transverse) sonogram in a healthy female volunteer. fc, false vocal cords; vc, true vocal cords; th, thyroid cartilage; tr, trachea.

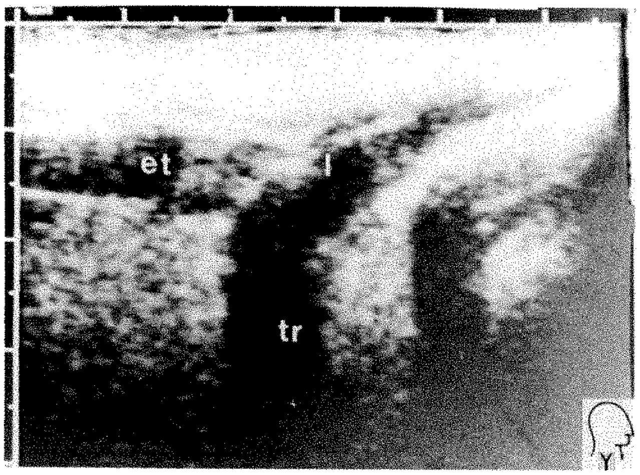

Figure 2. Laryngeal sagittal sonogram in a healthy male volunteer during oral ultrasound-guided endotracheal intubation. et, endotracheal tube; l, laryngeal inlet; tr, trachea.

refinements in this technique are needed before ultrasound will be a clinically useful aid to endotracheal intubation; however, ultrasound may prove to be a clinically useful tool for noninvasive examination of vocal cord movement.

Morbidity in the Postanesthesia Care Unit

To the Editor:

We agree with Hines et al. (1) that the postanesthesia care unit (PACU) period continues to be a source of morbidity. In a detailed prospective study (unpublished data), we evaluated 389 consecutive patients entering the PACU at a district general hospital. Using a standardized form based on the criteria of Zelcer and Wells (2), the incidence of PACU complications was determined. Each complication was confirmed by one of two anesthetists. Data showed that 32% (n = 124) of patients had 183 complications. Of the 183 complications, the most frequently encountered were pain (22.4%), a pulse oximeter reading <90% (14.8%), and, with agitation, hypotension and nausea, each accounting for 8.7%. According to ASA physical status, the percentages of patients with complications were ASA I 29% (n = 319), ASA II 38% (n = 61), ASA III 50% (n = 10), and ASA IV 100% (n = 3). The majority of patients (92%) recovered from anesthesia within 60 min of arrival in the PACU. The intraoperative complication rate was 14% (n = 55). Only 12 of the 55 patients with intraoperative complications had PACU complications.

We can thus confirm the appreciable morbidity of the PACU period, especially if the complications are deliberately sought. These surveys are of a useful audit of clinical practice. Although our specific findings can only apply to our institution, the general lessons learned can equally apply to other institutions where anesthetics are administered.

Combined Spinal and Extradural Anesthesia

To the Editor:

We read with interest the letter by Eldor et al. (1) describing the adaptation of the Tuohy needle for use in the combined spinal and extradural technique. Combined spinal and extradural anesthesia has become the technique of choice for most emergency and elective procedures performed under regional anesthesia in our obstetric unit. In fact, over the past 2 yr, we have performed more than 500 elective cesarean sections using this technique without ever having to resort to general anesthesia. This contrasts sharply with the stated incidence of 0.46%–35% failure rate with sole use of spinal anesthesia (2). We normally use a 26- or 27-gauge 120-mm-long spinal needle through a standard 16-gauge Tuohy needle and have encountered no serious complications. We believe that the adaptation of the Tuohy needle suggested in the letter by Dr. Eldor and colleagues is unnecessary and increases the technical difficulty of the procedure. The only theoretical advantage of this needle is that it may prevent the extradural catheter from accidentally passing through the hole made in the dura by the spinal needle. However, since the use of the needle-through-needle technique, first reported by Coates (3) in 1982, there has been no report in the international literature of an extradural catheter breaching the hole made by the spinal needle in the needle-through-needle technique. Combined spinal and extradural anesthesia has become increasingly more popular in our unit because it provides rapidity and density of spinal block, combined with the ability to extend the block and provide postoperative analgesia by use of the extradural catheter. It is also thought to be associated with a lower incidence of postdural puncture headache (4).

In Response:

In reply to Dr. Patel's letter concerning our combined spinal-epidural needle, newly named the Eldor needle, it is not only an "adaptation of the Tuohy needle," but a completely different concept in regional anesthesia.

I agree with Dr. Patel's description of the benefits of combined spinal-epidural anesthesia versus spinal anesthesia alone (or epidural anesthesia alone, which he did not mention); however, I disagree with him about the advantages or disadvantages of the Eldor needle compared with the needle-through-needle approach that he and his colleagues are using.

Using the Eldor needle, you can place the epidural catheter *before* inserting the spinal needle. In the Eldor needle, there is no risk of producing metallic particles while pushing the spinal needle through the bent-end portion of the Tuohy needle (1). With the Eldor needle, you do not need long spinal needles, which are more prone to fracture. These three advantages of the Eldor needle over the needle-through-needle approach are obvious and make it a superior approach.

I did not mention the danger of an inadvertent epidural catheter protruding to the spinal space through the hole made previously by the spinal needle, which Dr. Patel mentioned in his letter.

The Eldor needle does not "increase the technical difficulty of the procedure"; on the contrary, it decreases it. Perhaps Dr. Patel or one of his colleagues had difficulty placing the epidural catheter after the patient had received the spinal anesthetic injection. The small conduit attached to the side of the epidural needle in the Eldor needle does not create any technical difficulty, and the sensitivity is almost equal that of the original Tuohy needle. You can compare it to a spaceship on top of its missile.

Securing an Endotracheal Tube in the Presence of Facial Burns or Instability

To the Editor:

Temporarily securing the oral endotracheal tube in a patient with a burned or unstable face can be a difficult challenge. Facial fractures, with or without facial burns; loss of teeth, with or without facial fractures or burns; or a facial burn requiring debridement periorally all often present problems in terms of securing the oral endotracheal tube. The traditional approach has been to wire the endotracheal tube to a stable molar or to secure the tube to the face using standard or umbilical tape. Wire can cause damage to teeth, and tape, either standard or umbilical, is sometimes not optimal from a surgical standpoint nor safe from an anesthetic and patient standpoint. External taping can impede facial debridement, and the blood caused by debridement can loosen the tape, making an extubation or mainstem intubation more likely.

Another useful technique involves placing a heavy braided suture, such as 0 silk, circumferentially around the lingual base of teeth, which have a narrower apex than biting surface (Figure 1). Several knots complete the tie around the buccal surface. Approximately 2 cm above the knot that secures the tie around the tooth another knot is made. The endotracheal tube can then be secured against this knot. This creates a short leash for the endotracheal tube, which is anterior to the tooth, and facilitates visualization of the tube while effectively preventing significant upward and downward movement. Because the surgeon may wish to place his or her gloved finger in the oral cavity to facilitate the debridement, one should not tie around

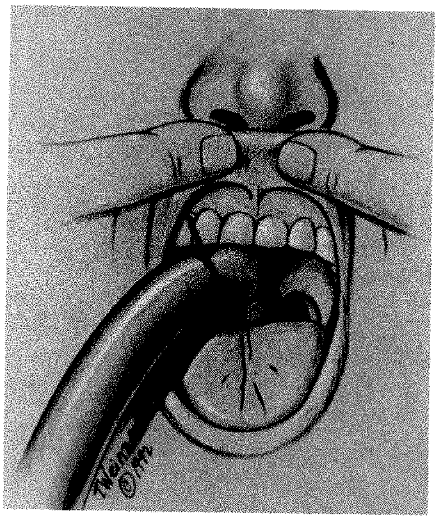

Figure 1. Heavy suture is placed around a tooth and a knot tied. A second knot alone creates a leash for the endotracheal tube.

both upper and lower teeth. The suture can easily be removed when extubation is appropriate by cutting it at the base of the tooth with a scalpel or needle edge.

Dr. Joseph Eastman Sheehan's Influence on the Introduction of Modern Anesthesia in Spain

To the Editor:

The Irish-born surgeon Joseph Eastman Sheehan (1885–1951) studied and practiced in the United States, achieving worldwide fame in the field of plastic surgery, for which he developed a number of widely adopted techniques. His wide-ranging interests also included cultural, social, and even diplomatic affairs (1). It was nevertheless in a professional and humanitarian capacity that he twice visited Spain.

In 1928, Sheehan came to Spain at the behest of King Alfonso XIII to treat patients suffering from the sequelae of wounds received in the Moroccan war (2). He operated on a number of facial paralysis cases at the Military Hospital of Madrid, was decorated by Alfonso XIII, and made numerous friends in Spanish society.

In 1937, during the Spanish Civil War of 1936–1939, Sheehan returned to Spain when the leader of the insurgent troops, General Franco, invited him to organize a military plastic surgery unit for the many casualties with severe face wounds (3). He was given the rank of honorary colonel and set up his unit at the General Mola Hospital in San Sebastian, behind the northern war front where most of the face wounds were produced. Not content with running the unit, which contributed greatly to the treatment of the wounded, Sheehan also organized training courses in plastic surgery that were attended by numerous military surgeons (4).

Among other problems to be overcome in setting up the plastic surgery unit were the outdated anesthetic practices of Spanish hospitals of the time. The usual procedure in operating theaters was for nurses or medical students to administer ether with the crude Ombredanne inhaler. Because this was totally inadequate for Sheehan's purposes, he sought the collaboration of Robert Macintosh, Professor of Anesthesia at the University of Oxford. Macintosh spent 6 wk in San Sebastian in late 1937 performing anesthesia with endotracheal intubation and in early 1938, was replaced by his colleague Kenneth Boston (5). Thanks to Sheehan's initiative, many Spanish surgeons had the opportunity to witness, and some to become familiar with, anesthetic techniques that were at that time unknown in Spain.

When on leaving Spain in the spring of 1938 Sheehan visited General Franco in Salamanca, he urged him to maintain the plastic surgery unit in service (1). Franco's response was to send the young Spanish military surgeon Sánchez Galindo to the United States to receive instruction, under Sheehan's patronage, in the foremost U.S. surgical clinics, where he learned both surgical techniques and the basics of modern anesthesia. On his return to Spain, he applied his new skills to war casualties; after the war, he continued to practice the anesthetic techniques he had learned in the Military Hospital of Madrid until the mid-1940s, when the first Spanish anesthesiology specialists were trained.

To conclude, we wish to pay tribute to Sheehan's memory for his professional, organizational, and humanitarian efforts in relation to the Moroccan uprising and the Spanish Civil War and for his tangible influence on the modernization of anesthesia in Spain.

The Element of Experience in Internal Jugular Vein Catheterization

To the Editor:

Hayashi et al. (1) assigned pediatric patients undergoing internal jugular vein catheterization (IJVC) to different operators in an attempt to learn whether experience was a factor that contributed to success or complication. The subject of percutaneous central venous access, both in adult and pediatric patients, has been widely addressed in journals and textbooks since being introduced more than 40 yr ago (2–5). First, the acquisition of this knowledge does not require years of experience or exposure. Second, technical facility (needle manipulation) is not very demanding and requires little practice to reach a reasonable level of proficiency. Third, the very act of "supervising" largely confers the knowledge of the supervisor on the operator. It is for these reasons that "experience" could not have had an effect in their study. Published in abstract form, we concluded in 1979 that the teaching of IJVC could be accomplished without significantly compromising the result (success/complication) in a nearly identical study with essentially the same results (6). This might have been a more appropriate conclusion for Hayashi et al. (1) on the basis of their study design.

More knowledge is required rather than practice of the technical component to increase success and to avoid puncture of the carotid artery. The success and carotid puncture rates are essentially predictable with the knowledge of the frequency with which the carotid artery and internal jugular vein bear a consistent relationship to the more superficial anatomic landmarks used. Denys and Uretsky (7) have provided data from ultrasound assessment in adults and found vascular position divergent from surface landmarks leading to failure or carotid puncture, or both, at a frequency of approximately 8%. Utilization of this knowledge (ultrasound visualization of exact rather than assumed location) during needle placement permits nearly 100% success and, with attention to detail, should eliminate carotid puncture (8).

It is logical to apply the ultrasound technology found to be successful in adults, because it appears that no significant improvement has occurred in IJVC in pediatric patients in more than 10 yr. It is likely that success rates and reduced complications will result in making IJVC more useful, safer, and more widely accepted. This would help to achieve one of the difficult goals of the clinician-educator: providing knowledge and skill for the student without compromising the result for the patient.

Dextran Absorption During Hysteroscopy With Hyskon, and the Biodegradation of Dextran

To the Editor:

In their article on dextran serum levels during hysteroscopic procedures with Hyskon, Mangar et al. (1) make an important contribution to our understanding of some adverse reactions observed during these procedures. Most of the side effects of Hyskon appear to be due to a sudden increase in circulating blood volume. Before this study, little was known of the extent to which Hyskon would pass into the intravascular compartment during various types of hysteroscopic procedures. This study has clearly demonstrated that at least one-third of the volume of Hyskon used can be fairly rapidly absorbed in connection with hysteroscopic ablation of the endometrium. It should be noted that the amounts of Hyskon used by the authors are within the recommended limits and that the procedures lasted <30 min. In contrast, most reports of adverse reactions have involved volumes exceeding the recommended limits; in some reports, >1000 mL has been used during long-lasting hysteroscopic surgery (2,3). In the abstract preceding the report, it is stated that the authors have correlated the amount of Hyskon used with instillation pressures, but the influence of pressure during injection of Hyskon is not clear from this article, because there seems to be a mistake with regard to the figures given on page 188; comparison with Figure 1 shows that the data reported represent the correlation between *dose* of Hyskon and serum levels. However, on page 189, the authors make a number of erroneous statements with regard to the biodegradation of Hyskon, claiming dextran 40 to be a product during this process and attributing this to a number of negative effects, such as elevations in blood glucose levels, errors in blood cross-matching, decreased platelet adhesiveness, renal failure, and decreased plasma levels of fibrinogen and of Factors V, VIII, and IX. Hyskon is composed of 32% dextran 70 and 10% glucose. Both dextran 70 and dextran 40 are mainly excreted in the urine in unaltered form, 50% and 70%, respectively, being excreted in this way within 24 h after a single dose. The larger molecules of either of these dextran fractions will gradually be absorbed into the reticuloendothelial system and degraded by the enzyme dextranase and subsequently metabolized to carbon dioxide and water, a process that will be completed in 2–3 wk. It is thus impossible for the "biodegradation" of dextran 70 to result in the patient accumulating dextran 40, which is composed of much lower molecular dextran fractions that are more easily excreted by the kidneys. Further, none of these dextran fractions will have a measurable influence on blood glucose levels, and the amount of glucose being supplied as such in the Hyskon solution would be small in the study patients, at most 20 g. Blood cross-matching is not influenced by modern dextrans to a degree that poses any problems in clinical practice, the effect of higher levels of dextran being only that of slightly increased rouleaux formation of the erythrocytes. Renal failure has on very rare occasions been observed after dextran 40 when high doses have been administered as the sole infusion to dehydrated patients but has not been reported after dextran 70. The effects of dextrans on platelet adhesiveness are specific, whereas the lowered levels of fibrinogen and coagulation factors appear to be related to hemodilution alone, according to a recent study (4). None of these effects can be labeled side effects, because they form at least part of the basis for the thromboprophylactic effect of dextrans, which is one of the main indications for the use of these agents.

4. Flordal PA, Svensson J, Ljungström K-G. Effects of desmopressin and dextran on coagulation and fibrinolysis in healthy volunteers. Thromb Res 1991;62:355–64.

In Response:

I would like to thank Dr. Ljungström for acknowledging our contribution to the understanding of some adverse reactions observed during hysteroscopy with Hyskon. As he correctly indicated, Figure 1 correlated the dose of Hyskon with serum levels. (The preceding sentence should have read, "A significant correlation between dose and serum levels. . . .") Because of the limitations of the hysteroscope, we were able to intermittently measure intrauterine pressures (10–160 mm Hg) when the surgical procedure could be halted. The Hyskon injection pressures were measured throughout the procedure (0.5–3.9 atm). Hence, correlating instillation pressure with doses was impossible, because intrauterine pressure could not be measured continuously.

Both dextran 40 and dextran 70 are polymers of glucose. Dextran 40 has 90% of its polymers with a molecular mass between 10,000 and 80,000 daltons. Dextran 70 contains polymers with molecular mass between 25,000 and 125,000 daltons (1,2). My hypothesis, which was not clearly stated in the article, was that dextran 40 possibly resulted from the disintegration of dextran 70. I agree with the reported route of elimination (3), as described by Dr. Ljungström.

We stated the adverse effects of dextran 40, which are clearly documented in the literature (1–11), and have seen no reference from Dr. Ljungström to support the contrary viewpoint. For example, we reported a "factitious" elevation in blood glucose because the blood glucose analysis required high acid hydrolysis concentration that may hydrolyze dextran to glucose. Dextran also produces a turbidity that interferes with orthotoluidine glucose measurements, resulting in a "factitious" elevation in blood glucose.

These "erroneous" statements, as described by Dr. Ljungström are in fact adverse reactions to dextran 40, and I was not implicating the reaction to dextran 70. Data and Nies (3) described seven paradoxes of dextran 40. These authors advise against using this agent so long as alternative therapy of equal efficacy and fewer side effects is available. One might question the use of dextran for thromboprophylaxis when other safe alternatives to dextran are available.

Bleeding diathesis exists after intravascular absorption, as demonstrated from published reports (12–18). A recent case report (18) describes a patient with extensive bleeding after 700 mL of intrauterine Hyskon, necessitating hysterectomy. Clearly, this is not only a dilutional effect (19), but a bleeding problem resembling a disseminated intravascular coagulation profile, possibly attributed to the effects of dextran 70. In most of the other published reports (12–17), the same bleeding pattern was seen.

Angioedema of the Tongue—Cause?

To the Editor:

A case report by Kharasch (1) discusses a 67-yr-old patient who developed angioedema of the anterior one-half of the tongue following extubation of the trachea after release of a Dupuytren's contracture under general endotracheal anesthesia. The author associates the angioedema with the initiation of enalapril, an angiotensin-converting enzyme (ACE) inhibitor, 10 days before surgery. Other causes of the angioedema are dismissed, even though enalapril is not clearly shown to be the cause. The possibility of hereditary angioedema, caused by deficiency of C1 inhibitor (C1 INH), is dismissed because the patient had no previous episodes of angioedema.

Angioedema after even mild trauma to tissue should always raise concern about C1 INH deficiency. Although patients with this hereditary disorder often present earlier in life, there are reports of patients presenting as late as the sixth decade of life (2–4). The average time from onset of symptoms until the diagnosis is made is 21 yr (2). In addition, acquired forms of C1 INH deficiency exist that typically present after the fourth decade (5). Acquired deficiency may be associated with benign or malignant B-cell proliferative states and essential cryoglobulinemia or may result from the idiopathic production of an autoantibody directed against the active site of the C1 INH molecule (6).

A rapid screening test for C1 INH deficiency is the C4 level. A low level suggests the diagnosis of C1 INH deficiency and may be followed with measurement of C1 INH antigenic levels and an assessment of its functional activity. Low C1 and C1q levels identify the acquired disease; C1 levels are normal in the hereditary form.

Recognition of C1 INH deficiency is paramount because treatment is drastically different in these patients than in those with angioedema that is allergic or idiopathic in origin. Patients with C1 INH deficiency generally do not respond to therapy with epinephrine, antihistamines, or glucocorticoids. Management of acute angioedema due to deficiency of C1 INH is difficult. Fresh-frozen plasma contains C1 INH but also contains the substrates for the enzyme, uncleaved C2 and C4. Theoretically, this may serve to fuel complement activation, and in practice, there are reports of patients worsening after administration of fresh-frozen plasma. In addition, administration of blood products carries the risk of possible infectious complications. Replacement therapy with purified C1 INH is available in Europe but not currently in this country.

Appropriate management of a patient with C1 INH deficiency involves preoperative recognition of the condition. Prophylaxis with anabolic steroids, such as oral danazol (600 mg daily) or stanozolol (6 mg four times a day) should be initiated 5–10 days before surgery (6). These attenuated androgens apparently enhance C1 INH synthesis. Thus, androgens provide effective prophylaxis without the increased risk of alternative preventative therapy with fresh-frozen plasma or ε-aminocaproic acid.

Certainly this patient may have had angioedema related to recent institution of enalapril or some other cause; however, deficiency of C1 INH, hereditary or acquired, has not been excluded.

In Response:

The case of ACE-inhibitor angioedema of the airway was reported to afford an awareness of this syndrome and its appropriate management among those potentially called on to secure the compromised airway of such afflicted patients. Drs. Maves and Weiler have expanded the dialogue to include hereditary angioedema. They describe eloquently the causes, proper evaluation, and appropriate management of C1 inhibitor deficiency.

These authors question whether a C1 inhibitor deficiency might have been the cause of the angioedema described in the case report. Two points deserve mention. First, C1 inhibitor deficiency is dismissed not only because the patient had had no previous episodes of angioedema during his 67 yr (1), but because he did have a normal C4 level (26 mg/dL; normal range 12–40 mg/dL) and normal C1 inhibitor activity (activity >95%; normal defined as >67%). Second, ACE-inhibitor airway angioedema is potentially life threatening and may recur even after apparent resolution (2,3). Laboratory evaluation of C1 inhibitor deficiency may take several days. Although it is certainly important to eventually rule out a C1 inhibitor deficiency, definitive therapeutic and preventative measures in a patient with suspected ACE-inhibitor angioedema should not await laboratory exclusion of other possible causes. The ACE inhibitors should be considered the cause of angioedema whenever it occurs in patients taking these drugs (4). The drug should be immediately discontinued, preferably by or in consultation with the prescribing physician.

Book Reviews

Contemporary Issues in Chronic Pain Management

W. C. V. Parris, ed. Boston: Kluwer Academic Publishers, 1991, 311 pp, $115.00.

Pain management is a rapidly emerging discipline. In the sphere of acute pain, new pharmacologic approaches, drug delivery systems, as well as organizations within the hospital community to deliver acute pain relief, have evolved only in the last few years. In the sphere of chronic pain, despite the general consensus on the efficacy of long-term opiate management of cancer pain, the rate of progress has been something less than a blur. Thorny problems continue to confront the clinician. Nevertheless, in certain areas, there is cause for quiet excitement.

Contemporary Issues in Chronic Pain Management seeks to give an honest appraisal of the state-of-the-art, candidly listing the assets and liabilities of this developing, and uniquely human, enterprise. New developments are held up as pearls of opportunity for the future (an asset), while much remains to be discovered (a liability). Despite the unevenness of its multiauthored prose, this text succeeds in convincing the reader that the assets well outweigh the liabilities, and that the enterprise is running well in the black.

The volume begins by taking a historical tack, examining whence pain management has come, that we may see wither it is going. In so doing, it confronts the highly charged political issues of: Who will lead? Who will govern? Who will be the standard-bearer, and more importantly, who will certify people for the practice of pain management? Will it be the American Pain Society, the American Academy of Pain Medicine, or will it be some other organization? I am sure that many readers eagerly wait to see what happens once the dust settles.

The chapter on how ethnicity, culture, and religion affect chronic pain, although perhaps not politically correct, was fascinating, entertaining, and fun reading. The myriad ways in which a person suffers when they are hurting probably has a great deal to do with who their parents were and what sort of society they came of age in. For the future, we can anticipate more revealing studies of this subject, whose surface has been barely scratched by researchers.

The fifth chapter by Harrison, titled "Endorphins and Narcotic Drugs: Pain Control Paradigms vs. Legal Realities" raises some very thought-provoking issues regarding the use of narcotics in the management of chronic pain. For example, at present, statutes do not discriminate between people who use narcotics to relieve their pain and people who abuse them for fun and profit, taring both groups with the broad brush of "Drug Addicted Person." We now know that our own bodies produce endogenous opiates (endorphins) that have the same effect upon the nervous system as the legally controlled group of substances called "narcotics," about which much criminal law is written. Given that, does it really make sense to stigmatize people with severe cancer pain, who use them for pain relief, as "drug-addicted persons"? Obviously not. The author suggests that our pharmacologic science has leapfrogged ahead of the law, developmentally speaking, and that now it is time for the law to play catch-up.

One of the causes for quiet excitement given excellent treatment is our evolving understanding of the pharmacology of substance P and related algesic substances acting at the level of the peripheral pain receptor, and the effectiveness of capsaicin, an extract of red pepper, at this level in the pain pathway. As author Szolcsanyi puts it, "There is a 'painfully' absent chapter in pharmacological textbooks, which could be entitled: 'Drugs acting on sensory neurons,' or 'Sensory neuron-blocking analgesics.'" In all, three authors speak about the substance P story, marshalling the evidence for its existence and its importance.

The editor offers up the interesting speculation that levels of substance P (as well as other neuropeptides) in different fluid compartments, such as blood, CSF, or even saliva, may serve as a correlate of, or biological marker for, chronic pain. If this is the case, then it follows that by monitoring levels of substance P, we can compare the effectiveness of old and new modalities of chronic pain therapy in an objective way. In an era of ascending cost-consciousness, such studies could carry enormous weight. In any event, it seems reasonable to think that the gap in our pharmacology textbooks alluded to by Szolcsanyi will be filled in the near future.

A chapter on nerve block therapy in chronic pain management by the editor was quite comprehensive and included pearls from the author's own practice about how to avoid pneumothorax in suprascapular nerve block. Neurolytic blocks for chronic cancer pain are mentioned in passing, and there is no mention of new developments such as superior hypogastric plexus neurolytic blocks, or ganglion impar blocks for the relief of pelvic and rectal pain, respectively. The natural history and treatment of reflex sympathetic dystrophy is well described.

A useful and interesting chapter on the history and state-of-the-art of thermography is provided. A final chapter on low-level laser biomodulation for chronic pain management contained the clearest explanation I have yet seen in the medical literature of how lasers function. The chapter rapidly became arcane and opaque when trying to show how this "solution in search of a problem" can be of help to the chronic patient.

In all, the editor succeeds in tying together many diverse subjects with a common thread. I would recommend this

©1992 by the International Anesthesia Research Society

book for people already involved in the practice of pain management, and for people who are well acquainted with pain management literature.

Anesthesia for Ophthalmic and Otolaryngologic Surgery

Kathryn McGoldrick, ed. Philadelphia: W.B. Saunders, 1992, 318 pp, $50.00.

Although there are many books available on subspecialty anesthetic practice, there is no current, comprehensive text dealing exclusively with anesthesia for otolaryngologic and ophthalmic surgery. As noted in the foreword to the book, this is remarkable, considering that anesthesia for ENT and eye procedures involve many challenges, including that of the shared airway. Fortunately, Kathryn McGoldrick and her colleagues have filled this void. *Anesthesia for Ophthalmic and Otolaryngologic Surgery* is a comprehensive, well-written text on the subject.

This reference work comprises 22 chapters, 16 of which were written or cowritten by the editor, Dr. McGoldrick. Consequently, it is cohesive and not overly repetitive. There is deliberate emphasis on anesthesia for pediatric and geriatric patients, as well as outpatients.

The book is divided into two sections. The first has 12 chapters devoted to anesthesia for otolaryngologic surgery and covers a wide range of topics including difficult intubations, pediatric airway emergencies, anesthesia for outpatient procedures, and laser surgery of the airway. These chapters are notable for their depth and clarity. For example, the chapter on anesthesia for elective otolaryngologic surgery includes a thorough discussion of the pathophysiology of patients, such as those with cystic fibrosis, who commonly present for ENT procedures. The chapter on anesthesia for airway emergencies discusses ordinary problems, such as the bleeding tonsil, as well as rare dilemmas like diphtheria.

As a reflection of the quality of the text and the clinical experience of the authors, facts accumulated from numerous investigations are usually synthesized into a cohesive set of conclusions; however, although most of the facts are supported with a substantial number of references, this is not consistently the case and may be improved upon in subsequent editions. There is an element of "cookbook" style in several of the chapters, but usually the "recipes" are guides and follow a scholarly discussion of the competing issues of particularly difficult clinical problems (epiglottis, open globe/full-stomach, etc.). The authors go to great lengths to emphasize that there may be several correct methods of patient management in some situations.

The second section deals primarily with anesthesia for eye surgery. It discusses many topics that anesthesiologists will be thankful to find consolidated in one text. These include anatomy and physiology of the eye, anesthetics and intraocular pressure, pediatric ophthalmologic surgery, ocular pathology and systemic diseases, and anesthetic ramifications of ophthalmic drugs. This section also displays substantial depth and is quite comprehensive. For example, the chapter on ocular pathology and systemic diseases engages in a scholarly review of congenital and metabolic disorders associated with ocular disease. The detailed information on 18 syndromes is consolidated in concise tables for easy reference when these patients (mainly children) present for eye surgery, often on an ambulatory basis.

In summary, Dr. McGoldrick and her colleagues have provided us with a tremendously useful resource. This book is comprehensive, well-written, and scholarly. At $50 it is an excellent value. It is very highly recommended for anesthesia libraries or for the personal collection of anesthesiologists who care for patients undergoing otolaryngologic or ophthalmic surgery.

Mechanisms of Anesthetic Action in Skeletal, Cardiac and Smooth Muscle. Volume 301 in Experimental Medicine and Biology Series.

Thomas J. J. Blanck and David M. Wheeler, eds. New York: Plenum Press, 1991, 310 pp, $79.50.

This book presents the results of a symposium held in 1990, the purpose of which was to simultaneously gather at Johns Hopkins University School of Medicine many of the people currently working in areas related to the pharmacodynamics of the volatile anesthetics in the three major categories of muscle. Because many of the contributors are recognized experts in their respective fields, the product of their collective presentations represents not only a display of the good science typical of these individuals, but also an education in the modern physiologic and biochemical techniques applied to this topic. Furthermore, the new data presented are built on very recent advances already made in the cell biology of each muscle type (e.g., malignant hyperthermia for skeletal muscle, receptor biology for cardiac muscle, and the interaction of the vascular endothelium with vascular smooth muscle). Recognition that these fields are not mutually independent is provided in a chapter dealing with coronary vascular smooth muscle reactivity in situ; that is, coronary blood vessels situated in their natural physical environment in close proximity to, and undoubtedly affected by, cardiac muscle. One is struck by the inventive experimental approaches used to separate the effects of anesthetics on each muscle type in such a preparation and by the relatively close agreement shown using widely diverse experimental systems when applied to selected hypotheses. Lest one be comforted by the prospect of unanimity of expert opinion with regard to the behavior of muscle under anesthesia, however, the book makes clear that there is still serious disagreement concerning fundamental mechanisms at work in this broad and active field.

The first section of the book addresses the effects of anesthetics on skeletal muscle and emphasizes recent advances in the cell biology of malignant hyperthermia (MH). Early in the section, some basic membrane functional abnormalities of MH are discussed, specifically with regard to mitochondria, sarcoplasmic reticulum (SR), and the sarcolemma. Attention is given to recent work supporting a role of abnormal lipid metabolism as a basis for MH; however, experiments with cyclooxygenase inhibitors and lipoxygenase inhibitors have suggested no role for prostaglandins, leukotrienes, or thromboxanes in the abnormal sodium channel function in cultured human MH skeletal muscle cells, as determined by measurements of inward tetrodotoxin-inhibitable sodium currents. Rather, the effects of unsaturated fatty acids on lowering the threshold for calcium-induced release of calcium accumulated by the isolated heavy subfraction of the SR from MH skeletal muscle are emphasized. This threshold, found to be lower in the presence of halothane, is the centerpost of a proposed mechanism favored by some to explain MH. The fact that this curious effect of halothane and other anesthetic gases appears only in genetically susceptible individuals is attributed by these investigators to the presence of a recently discovered genetic abnormality of the calcium release channel of the SR in the Pietrain strain of pig, an MH-susceptible strain used in some laboratories investigating the molecular and cell biology of MH. However, the link between halothane sensitivity and the apparent substitution of a single amino acid in the primary sequence of the calcium release channel protein seems too easily made. These proponents point to an altered binding of the plant alkaloid, ryanodine, to Pietrain-derived SR calcium release channel compared with that of their normal Yorkshire porcine counterparts as direct evidence for a difference in functional behavior between the two proteins. Chapter 6 of the book describes the same ryanodine experiments in normal and susceptible individuals of the same strain of pig (Yorkshire X Duroc cross) and shows essentially identical binding characteristics between the normal and MH conditions. The conclusion seems to be that the previously discovered difference in ryanodine binding was a strain-specific effect rather than a disease-specific effect and that, at least in pigs, not all cases of MH susceptibility are necessarily due to a primary abnormality in the calcium release channel. (It is virtually certain, from genetic linkage studies, that the same is also true for human beings.)

The next section of the book, which covers the effects of anesthetics on cardiac muscle, begins with one of the most revealing chapters in the book, which attempts to bridge the gap between the increased contractility in skeletal muscle and decreased inotropism in cardiac muscle caused by volatile anesthetics. The chapter does so by relating these two opposite tissue effects to the common response of both types of SR to halothane, which is an increased calcium efflux while not affecting the calcium uptake mechanism at clinical concentrations. In skeletal muscle, in which the activating calcium cycles almost exclusively internally throughout the muscle twitch, enhancement of twitch tension is the expected result of halothane exposure. In the smaller cardiac myocyte, however, some activating calcium, after release from the SR during systole, may more likely be rapidly extruded from the cell via the surface membrane calcium pump or facilitated exchange with extracellular sodium ion. This would leave a decreasing fraction of the calcium released by the SR on physiologic activation to be reaccumulated by the SR during diastole over the several beats after the initial exposure. The result of less calcium uptake by the SR is that less is released during subsequent systoles, hence, the negative inotropic effect of halothane. Although this explanation ignores effects of anesthetics on "upstream" calcium flux across the sarcolemma as well as effects on "downstream" calcium binding sensitivity of troponin, these issues are elegantly treated in subsequent chapters in this section that show the delicacy and complexity of the interaction of anesthetics with the heart.

The final section of the book discusses vascular smooth muscle responses to anesthetics. Here, a complicating factor must be considered, that of the vascular endothelium, which produces the recently popularized nitric oxide, a component of the endothelial-derived relaxing factor, or EDRF, as a possible target of anesthetic modification of vascular smooth muscle tone. Therefore, as in cardiac muscle, anesthetic effects on all components of excitation-contraction coupling must be considered, but additional attention must be paid to anesthetic-induced alterations in the function of the nearby vascular endothelium. Accordingly, this section of the book is the most complex and difficult to follow of the three. One finds agent-dependent effects on smooth muscle tone that may or may not change after removal of the endothelium, and one finds effects dependent on the particular vascular bed under study. Finally, whether vascular smooth muscle relaxation or contraction is observed may also depend on the concentration of anesthetic applied and the degree of preactivation produced by added vasocontrictor before addition of anesthetic to maximize possible relaxing effects of the latter. What emerges from the plethora of data and discussion is that there has yet to be proposed a unifying concept to explain the apparently contradictory results in this arena. This may not be surprising, because the apparently universal observation of diminished calcium influx into cells caused by anesthetics might theoretically cause a direct relaxation of vascular smooth muscle as well as decrease the calcium-dependent production of endothelial-derived relaxing factor by endothelial cells, with an experimentally unpredictable overall result on vascular tone.

Finally, on pondering the various methodologies described in the book, one can only be impressed at the wide range of experimental approaches used in this important problem and cannot help but become better educated by reading about them. Although the book is complex and written at a relatively high level for the practicing clinician without special training in the relevant experimental techniques, the reader emerges from the exercise as a more sophisticated critic of the science behind the practice of clinical anesthesia.

University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Handbook of Mechanical Ventilatory Support

A. Perel and M. C. Stock, eds. Baltimore: Williams & Wilkins, 1992, 308 pp, $35.00.

An English professor of mine once advised his students that the key to effective writing was, "Know what you want to say and say it." That is exactly what this book does. This primer discusses the physiology and practical aspects of various types of mechanical ventilation in the critically ill. The chapters, for the most part, are concise, direct, and well written by experts with both knowledge and experience in critical care medicine.

The book is divided into three sections. The first section discusses the physiology of mechanical ventilation in various organ systems. These chapters are clinically helpful, and one can imagine a house officer reading them at 2 AM. One exception in the practical bent of the handbook is the pulmonary section, which includes an extensive discussion of experimental animal models of lung injury.

The second section covers the spectrum of ventilatory modes. This section is an excellent resource in that it describes all the major ventilatory modes that are available today, with practical tips on how to use the equipment that is currently available. This information will assist the clinician trained in an earlier era as well as the house officer in deciding among the increasing options for ventilatory support.

The third section applies the principles and mechanical techniques of ventilatory support to specific disease states, such as acute lung injury, COPD, asthma, trauma, and weaning techniques. The last chapter is a summation of the various ventilatory modes contrasting the risks and benefits of each one.

Overall, this book is informative and easy to read, and abbreviations and repetition are avoided. The diagrams, flow charts, and tables throughout the chapters add greatly to the book's usefulness. As an inexpensive, portable handbook, it is a "must buy" for the experimental clinician as well as the house officer on an intensive care unit rotation.

Doris K. Cope, MD
University of South Alabama
Mobile, Alabama

Clinical Anesthesiology

C. E. Morgan and M. S. Mikhail. East Norwalk, Connecticut: Appleton & Lange, 1992, 747 pp, $39.95

Current anesthesia texts can be divided into three categories: the comprehensive, extensively referenced, authoritative textbook (e.g., Miller, Barash), the introductory textbook (e.g., Dripps/Eckenhoff/Vandam), and the handbook (e.g., MGH, baby Barash). Each of the three types addresses a specific audience and fulfills a specific need. *Clinical Anesthesiology* contains features of all three types. Although paperbound, it is a full-size book that is significantly more comprehensive than typical handbooks and introductory texts. The book covers five sections: anesthesia equipment and monitors; clinical pharmacology; regional anesthesia and pain management; physiology, pathophysiology, and anesthetic management (of specific organ systems, disease states, and procedures); and special problems. The two authors (responsible for 45 of the 48 chapters) write in a clear, straightforward style that is frequently supplemented by illustrations and tables. Each chapter is followed by a case discussion. Although this format could have reinforced important concepts, I frequently found that the case discussion involved core information that should have been directly included in the chapter (e.g., the difficult airway) or information that was relatively esoteric.

In the preface, the authors state that the book is written "primarily for newcomers to the specialty"; however, with over 700 pages of fact-filled text, this book cannot be read during a medical school clerkship or in the beginning weeks of anesthesia training. Thus, this book does not replace the standard introductory texts and handbooks. At the other extreme, the book does not contain the detailed, referenced information (particularly in the subspecialties) needed during the full anesthesia residency and clinical practice. In many respects, the book contains the full knowledge base expected of a resident midway through his anesthesia training. The modest price, size, and weight suggest that this would be an excellent book for residents to use during their first two years.

The text has a significant number of typographical errors that may mislead the reader. For example, the equation for calculating mitral valve flow (page 325) uses diastolic filling pressure rather than diastolic filling period. Table 4-2, describing anesthesia apparatus checkout recommendation, states "20 cm N_2O" rather than "20 cm H_2O." These errors should have been found with careful proofreading.

In summary, *Clinical Anesthesiology* is more comprehensive than the introductory textbooks and handbooks but more readable than the authoritative textbooks. I recommend it for those residents and clinicians who will find such a book to be valuable.

A Guide for Authors

Manuscripts should be sent to:

King C. Kryger, PhD
Managing Editor
Anesthesia & Analgesia
3497 Sacramento Street
San Francisco, CA 94118

Editorial Policies

Anesthesia & Analgesia, the oldest publication for the specialty of anesthesiology, is the official voice of the International Anesthesia Research Society. It publishes original articles, case reports, technical communications, review articles, special articles, medical intelligence articles, editorials, book reviews, and letters to the editor. Original articles will, when possible, be assigned to one of the subspecialty sections (Ambulatory Anesthesia, Cardiovascular Anesthesia, Critical Care and Trauma, Neurosurgical Anesthesia, Obstetric Anesthesia, Pediatric Anesthesia, and Regional Anesthesia and Pain Management). All papers are reviewed by three or more referees. Acceptance is based on significance, originality, and validity of the material presented. Only one copy of an article not accepted for publication will be returned to the author.

The submitted manuscript should be accompanied by a cover letter that includes a statement to the editor about all submissions and previous reports that might be regarded as prior or duplicate publication of the same, or very similar work. The title page and abstract of such material should be included with the submitted manuscript to help the editor decide how to deal with the matter. Manuscripts must be prepared and submitted in the manner described in "Uniform Requirements for Manuscripts Submitted to Biomedical Journals," reprinted in *The New England Journal of Medicine* 1991;324:424–8.

No manuscripts describing investigations carried out in humans will be accepted for publication unless the text states that the study was approved by the authors' institutional human investigation committee and that written informed consent was obtained from all subjects or, in the case of minors, from parents. No manuscript describing investigations in animals will be accepted for publication unless the text states that the study was approved by the authors' institutional animal investigation committee. Human subjects should not be identifiable. Do not use patients' names, initials, or hospital numbers.

Authors and their typists should use the checklist given below for preparation of manuscripts:

General

☐ Original articles, in 3000 words or less, describe clinical or laboratory investigations.

☐ Case reports, in 1000 words or less, describe either new and instructive cases, anesthetic techniques and equipment of demonstrable originality, usefulness, and safety, or new information on diseases of importance to anesthesia.

☐ Technical communications, of 1500 to 2000 words, describe instrumentation and analytic techniques.

☐ Review articles, of 2500 to 4000 words, collate, describe, and evaluate previously published material to aid in evaluating new concepts.

☐ Medical intelligence articles, of 1500 to 4000 words, usually collate, describe, and evaluate previously published material to aid in evaluating new concepts or updating old concepts or topics germane to anesthesiology.

☐ Special articles, of 2500 to 4000 words, describe literature, education, societies, and other topical interests of a historical or current trend in anesthesiology.

☐ Editorials (solicited by the Editorial Board), in 2000 words or less, comment on articles published in the journal and/or express the general policies or opinions of the Editor-in-Chief.

☐ Book reviews, in 1000 words or less, report on current literature available in anesthesiology.

☐ Letters to the editor, of 300 words or less, include brief constructive comments concerning previously published articles or brief notations of general interest. The manuscripts must be double-spaced, and a title and three copies must be provided. When letters concern a previously published article, the author(s) of that article will be invited to respond and both the response and the letter will be published together. Otherwise, accepted letters will be published without a response.

☐ Type manuscripts on white bond paper, 216 by 279 mm (8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 25 mm (1 in.) using double- or triple-spacing (to allow room for editing) throughout, including references and table and figure legends.

☐ Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, tables (each table, complete with title and footnotes, should be on a separate page), and legends. Type only on one side of the paper and number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

☐ Submit one original plus three copies of the manuscript and four sets of figures in a heavy paper envelope. Submitted manuscripts should be accompanied by a cover letter and by letters granting permission to reproduce previously published materials or to use illustrations that may identify subjects.

☐ Authors should keep copies of everything submitted and all correspondence from the editorial office and its board members.

Title Page

☐ The title page should contain the title of the article, which should be concise but informative;

☐ A short running head of no more than 40 characters (count letters and spaces) placed at the bottom of the title page and identified;

☐ First name, middle initial, and last name of each author, with highest academic degree(s) including fellowship and board affiliations; each listed author must (a) have participated in the work to the extent that he or she could publicly defend its contents; (b) have read the manuscript before its submission for publication; and (c) be prepared to sign a statement to the effect that he or she has read the manuscript and agrees with its publication. Additional names of author(s) may not be appended after sending revised manuscript to the journal without written consent from the senior author and approval on a case-by-case basis from the Editor-in-Chief;

☐ Name of department(s) and institution(s) to which the work should be attributed;

☐ Disclaimers, if applicable;

☐ Name, address, telephone number, and FAX number of author responsible for correspondence about the manuscript;

☐ Name and address of author to whom requests for reprints should be addressed, or a statement that reprints will not be available from the author;

☐ The source(s) of support in the form of grants.

Abstract and Key Words

☐ The second page should carry an abstract of not more than 150 words. (Abstracts are needed only for original articles.)

☐ The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals; observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations.

☐ Define all abbreviations except those approved by the International System of Units.

☐ Key (indexing) words. Below the abstract, provide (and identify as such) 3 to 10 key words or short phrases that will assist indexers in cross indexing the article.

Text

☐ The text of observational, experimental, and original articles is usual-

©1992 by the International Anesthesia Research Society

ly—but not necessarily—divided into sections with the following headings: Introduction, Methods, Results, and Discussion.

☐ *Introduction:* Clearly state the purpose of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references and do not review the subject extensively.

☐ *Methods:* Describe the selection of observational or experimental subjects (patients or experimental animals, including controls) clearly. Identify the methods, apparatus (manufacturer's name and address in parentheses), and procedures in sufficient detail to allow other workers to reproduce the results. Give references to established methods, including statistical methods; provide references and brief descriptions for methods that have been published but are not well known; describe new or substantially modified methods, give reasons for using them, and evaluate their limitations.

☐ Identify precisely all drugs and chemicals used, including generic name(s), dosage(s), and route(s) of administration. In the body of the text, cite the drug or chemical name followed by the generic name in parentheses and refer to the drug throughout the text by its generic name.

☐ *Results:* Present the results in logical sequence in the text, tables, and illustrations. Do not repeat in the text all the data in the tables and/or illustrations; emphasize or summarize only important observations.

☐ *Discussion:* Emphasize the new and important aspects of the study and conclusions that follow from them. Do not repeat in detail data given in the Results section. Include in the Discussion the implications of the findings and their limitations and relate the observations to other relevant studies. Link the conclusions with goals of the study but avoid unqualified statements and conclusions not completely supported by the data.

☐ *Units of measurement:* Measurements of distance/length and weight must be expressed in metric units only. Clinical laboratory and hematologic data must be expressed in **SI units** with, if desired, present conventional metric units in parentheses.

References

All references must be available to all readers. Cite only references to books and articles or abstracts published in peer-reviewed *Index Medicus* journals. Abstracts appearing only in programs of meetings are not acceptable, nor are abstracts more than five years old.

☐ Number references consecutively in the order in which they are first mentioned in the text.

☐ Identify references in text, tables, and legends by arabic numerals (in parentheses, on line)

☐ Use the style of the examples below, which are based on the format used by the US National Library of Medicine in *Index Medicus.*

☐ The titles of journals must be abbreviated according to the style used in *Index Medicus.*

☐ References must be verified by the author(s) against the original documents, and the entire list must be checked for nonduplication.

Examples:

1. *Standard journal articles* (List all the authors when four or less; when five or more, list only the first three and add et al.)
   Rigler ML, Drasner K, Krejcie TC, et al. Cauda equina syndrome after continuous spinal anesthesia. Anesth Analg 1991;72:275–81.
2. *Personal author(s) of books and monographs*
   Eisen HN. Immunology: an introduction to molecular and cellular principles of the immune response. 5th ed. New York: Harper and Row, 1974.
3. *Chapter in a book*
   Weinstein L, Swartz NM. Pathogenic properties of invading microorganisms. In: Sodeman WA Jr, Sodeman WA, eds. Pathologic physiology: mechanisms of disease. Philadelphia: WB Saunders, 1974:457–72.

Tables

☐ Type each table double-spaced on a separate sheet. Do not submit tables as photographs.

☐ Number tables consecutively and supply a brief title for each. Give *each* column a short or abbreviated heading.

☐ Place explanatory matter in footnotes, not in the heading. (In footnotes, define all abbreviations that are used in each table.) For footnotes, use lower-case italicized letters in alphabetical order.

☐ Do not use internal horizontal or vertical rules.

☐ Cite each table in the text in consecutive order.

☐ If data are used from another published (or unpublished) source, submit written permission from both author and publisher and acknowledge fully.

Illustrations

☐ Submit a complete set of figures with the original and each copy of the manuscript (4 sets total). Two sets must contain glossy illustrations, the other two sets may be high-quality photocopies. Figures must be in black and white and must be professionally drawn and photographed; freehand or typewritten lettering is unacceptable. Note: Art work of published articles will not be returned.

☐ Send sharp, unmounted, glossy black-and-white photographic prints, usually 127 by 173 mm but no larger than 203 by 254 mm, instead of original drawings, roentgenograms, or other material.

☐ Many computer-generated figures are unsatisfactory for reproduction and should be professionally redrawn. Lettering should be of adequate size to retain clarity after reduction (*final* lettering size in print should be 1.5 mm high). Symbols, cross-hatching, and stippling within a figure should be sharp and distinct enough to retain uniqueness after reduction.

☐ Each figure must have a label pasted on its back indicating the number of the figure, the names of the authors, and the top of the figure. Do not write on the back of the figures. Do not mount them on cardboard or scratch them by using paper clips. Do not bend figures.

☐ Photomicrographs must have internal scale markers. Symbols, arrows, and letters used in the photomicrographs should contrast with the background.

☐ Cite each figure in the text in consecutive order. If a figure has been published, acknowledge the original source and submit written permission from both the author and the publisher to reproduce the material. Permission is required, regardless of authorship or publisher, except for documents in the public domain.

☐ If a human subject is identifiable in the illustration, written consent must be obtained from the patient or legal guardian.

Legends for Illustrations

☐ Type legends for illustrations double-spaced starting on a separate page, with arabic numerals corresponding to the illustrations.

☐ When symbols, arrows, numbers, or letters are used to identify parts of the illustrations, identify and explain each one clearly in the legend.

☐ Define all abbreviations used in each illustration.

Abbreviations

☐ **At first mention of terminology in text, spell out in full and follow immediately with the abbreviation (enclosed within parentheses).**

☐ **Do not synthesize new or unusual abbreviations. When many abbreviations are used, include all in a box of definitions at the start of the article.**

☐ **Consult the following sources for abbreviations:**

1. **CBE Style Manual Committee. Council of Biology Editors style manual: a guide for authors, editors, and publishers in the biological sciences. 5th ed. Bethesda, Maryland: Council of Biology Editors, 1983;**
2. **American Medical Association. Manual of style. 8th ed. Baltimore, Maryland: Williams & Wilkins, 1989.**

Exclusive Publication Statement

☐ The principal author of all materials submitted for publication (except letters to the editor) must include in a cover letter a statement to the effect that none of the material in this manuscript has been published previously nor is any of this material currently under consideration for publication elsewhere.

☐ Authors will be asked to transfer copyright of articles accepted for publication to the International Anesthesia Research Society.

CLASSIFIED ADS

Anesthesia & Analgesia makes available classified advertising space for those interested in obtaining positions or wishing to announce meetings, postgraduate courses, or other pertinent events. We require that all advertisements be relevant to the practice of anesthesia and analgesia, and we reserve the right to refuse advertisements that are not relevant.

Specifications. Ads should be typewritten on letterhead stationery; the text should be double-spaced, with the title or key phrase typed in capital letters. Enclose two photocopies with each ad. Display space (minimum ¼ page) is available through Pharmaceutical Media, Inc., 440 Park Avenue South, 14th floor, New York, NY 10016, telephone: (212) 685-5010, FAX: (212) 685-6126.

Rates. Ads cost $1.50 per word per insertion, with a minimum of 20 words. Abbreviations, dates, initials, post office box numbers, telephone numbers, years, and zip codes are considered one word each. There is an additional fee of $18.00 per insertion for box number ads.*

Payment. Full payment or institutional purchase order must accompany the copy for each ad. Ads received without a check or purchase order will be returned. (Make checks payable to Elsevier Science Publishing Company, Inc.)

Deadline. Copy must be received 7 weeks before publication date (i.e., by January 1 for the March issue); multiple-insertion ads are welcome. Ads may run up to 6 months per purchase order/payment. Please specify in which issue(s) your advertisement is to appear.

Send all ad copy, payments, and correspondence to: *Anesthesia & Analgesia*, Classified Ads, Desk Editorial, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

*When responding to a box number ad, include the box number on all correspondence.

ulum vitae, bibliography, and the names and addresses of three references to John Zanella, Jr, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of Tennessee, Memphis, 800 Madison Avenue, Memphis, TN 38163. The University of Tennessee is an Equal Opportunity Employer/Affirmative Action Register/Title IX/Section 504 Employer.

DON'T FAIL THE WRITTEN BOARDS!
Unique study program including memory devices, methods for improved retention, guessing techniques, etc. Practice questions with answers, explanations and references, new Keywords. Get MEDTEXT not imitations. Call 1-800-695-6301 for information 24 hours. Call 1-800-232-TEXT for orders. MC/V accepted.

933H/A

TUTORING FOR WRITTEN AND ORAL BOARD EXAMS
The unique feature of these programs is the maximum class size of four students. Preparation for the written and oral exams are given separately in 3-day blocks in San Francisco and New York. FOR THE WRITTENS, techniques are taught for dealing with the multiple-choice questions. The basic sciences are stressed. FOR THE ORALS, the guided case discussions are stressed. Home study programs are provided. CALL (415) 321-1117.

The Osler Institute

Surgery Boards Review Course

October 14-20, 1992 – Chicago

Nov. 6-8 – Cleveland Dec. 11-13 – Chapel Hill Feb. 5-7, '93 – Dalla

Now, your course for written and oral boards offers unlimited mock exam

OBJECTIVES

- Increase knowledge of surgical principles and practice
- Prepare candidates to take written and oral board exams
- Provide a comprehensive review for recertification

METHODS

- HOME STUDY questions, assignments and answers
- SEMINAR with slides and syllabus (Part I course only)
- PRACTICE EXAMS for your oral boards

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities, but from people who are relatively unknown as well."**

Part I Courses:

October 14-20 – Chicago

The Part I Course is designed to prepare candidates for written and oral exams. The course will include home study materials, seven days of lectures with projection slides and syllabus, and practice oral exams. The course in Chicago is immediately before written exams.

Part I Topics

Basic Surgery

Anatomy and Physiology
Anesthesiology
Shock, Fluids and Lytes
Bleeding and Transfusion
Nutritional Support
Surgical Oncology
Transplantation
Infection and Sepsis
Pre- and Post-op. Care

General Surgery

Alimentary Tract
Liver and Gallbladder
Abdomen and Hernia
Pancreas and Spleen
Retroperitoneum
Breast and Skin Tumors
Endocrine Surgery
Head and Neck Surgery
Trauma and Burns
Surgical Critical Care

Special Surgery

Thoracic Surgery
Cardiac Surgery
Vascular Surgery
Orthopedic Surgery
Pediatric Surgery
Urologic Surgery
Gynecologic Surgery
Neurosurgery
Ophthalmology
Plastic Surgery

Faculty

Robert Arensman, M.D.
Robert Bahnson, M.D.
Mimis Cohen, M.D.
John Corson, M.D.
Edward Czinn, M.D.
Robert Feder, M.D.
T. Bruce Ferguson, M.D.
John Fildes, M.D.
Charles Goldman, M.D.
Gerald Harris, M.D.
Edwin Kaplan, M.D.
Mary Jeanne Krob, M.D.
Eberhard Mammen, M.D.
Gary Merlotti, M.D.
Raymond Pollack, M.D.
Harry Richter, M.D.
Natan Scher, M.D.
Joseph Vitello, M.D.
David Vogt, M.D.
Robert Wilson, M.D.

Part II Courses:

November 6-8 – Cleveland
Dec. 11-13 – Chapel Hill
February 5-7, 1993 – Dallas

The Part II Course is designed to prepare board candidates for oral exams. The course will consist of mock oral exams, each based on a presenting problem leading to questions on differential diagnosis, treatment options and complications. Faculty will critique each exam and answer questions.

Each participant will have an exam and critique session and unlimited observation of other sessions. Additional 25-minute sessions may be arranged for $70, and private sessions may be arranged for $100.

Part II Topics

Alimentary Tract
Liver and Gallbladder
Abdomen and Hernia
Pancreas and Spleen
Breast and Skin Tumors
Endocrine Surgery
Head and Neck Surgery
Thoracic Surgery
Vascular Surgery
Trauma Management
Surgical Critical Care

*"...remarkably complete and pleasant...."**

COURSES: The Part I course (consisting lectures and evening mock oral exams) is giv a month before and the week before writt and recertification exams. The Part II cour (mock oral exams) is given for three da before and in the same city as each oral exa Each participant is guaranteed a one-on-o public mock oral and can purchase addition public or private exams. Past participants re ommend repeating our courses, for half pric immediately before your exam.

*"...Accommodations were comfortable...."**

LOCATION: The Part I course will be at th Lisle/Naperville Hilton – 20 miles southwe of Chicago's O'Hare airport. Room rates a $85 for a single and $110 for a double. Th Part II course hotels will be selected in con petitive bidding for the best combination good rates and excellent study environment.

*"...and those little extras...."**

DISCOUNT AIR FARES: Please call toll free (800) 356-7537 for group discount rates.

*"...the most education for the money."**

FEES AND COURSE HOURS:

Surgeon or Resident:	**Surg.**	**Res.**	**Hr**
• Part I course (7 days):	$810	$540	6.
repeating within 2 years:	$405	$405	6
• Part II course (3 days):	$600	$400	2.
repeating within 2 years:	$300	$300	2
• Extra mock oral exam:	$ 80	$ 80	1/
• Private mock oral exam:	$110	$110	1/

- **Add 10% within 10 days of the course.**
- Not in course hotel package add $25 per day.
- $50 will reserve your position.
- Most home study materials will be mailed after half of the registration fee is recieved.

"...home study material was extremely helpful."

REFUNDS: Subject to a $50 fee, refund will be made until the beginning of the semina

*"I feel [the course] helped me pass..."**

Alfenta®
(alfentanil HCl) Injection CII

Before prescribing, please consult complete prescribing information, of which the following is a brief summary.

CAUTION: Federal Law Prohibits Dispensing Without Prescription
DESCRIPTION: ALFENTA is a sterile, non-pyrogenic, preservative free aqueous solution containing alfentanil hydrochloride equivalent to 500 μg per ml of alfentanil base for intravenous injection. The solution, which contains sodium chloride for isotonicity, has a pH range of 4.0-6.0.
CONTRAINDICATIONS: ALFENTA (alfentanil hydrochloride) is contraindicated in patients with known hypersensitivity to the drug.
WARNINGS: ALFENTA SHOULD BE ADMINISTERED ONLY BY PERSONS SPECIFICALLY TRAINED IN THE USE OF INTRAVENOUS AND GENERAL ANESTHETIC AGENTS AND IN THE MANAGEMENT OF RESPIRATORY EFFECTS OF POTENT OPIOIDS. AN OPIOID ANTAGONIST, RESUSCITATIVE AND INTUBATION EQUIPMENT AND OXYGEN SHOULD BE READILY AVAILABLE. BECAUSE OF THE POSSIBILITY OF DELAYED RESPIRATORY DEPRESSION, MONITORING OF THE PATIENT MUST CONTINUE WELL AFTER SURGERY. ALFENTA (alfentanil hydrochloride) administered in initial dosages up to 20 μg/kg may cause skeletal muscle rigidity, particularly of the truncal muscles. The incidence and severity of muscle rigidity is usually dose-related. Administration of ALFENTA at anesthetic induction dosages (above 130 μg/kg) will consistently produce muscular rigidity with an immediate onset. The onset of muscular rigidity occurs earlier than with other opioids. ALFENTA may produce muscular rigidity that involves all skeletal muscles, including those of the neck and extremities. The incidence may be reduced by: 1) routine methods of administration of neuromuscular blocking agents for balanced opioid anesthesia; 2) administration of up to ¼ of the full paralyzing dose of a neuromuscular blocking agent just prior to administration of ALFENTA at dosages up to 130 μg/kg; following loss of consciousness, a full paralyzing dose of a neuromuscular blocking agent should be administered; or 3) simultaneous administration of ALFENTA and a full paralyzing dose of a neuromuscular blocking agent when ALFENTA is used in rapidly administered anesthetic dosages (above 130 μg/kg). The neuromuscular blocking agent used should be appropriate for the patient's cardiovascular status. Adequate facilities should be available for postoperative monitoring and ventilation of patients administered ALFENTA. It is essential that these facilities be fully equipped to handle all degrees of respiratory depression.
PRECAUTIONS: DELAYED RESPIRATORY DEPRESSION, RESPIRATORY ARREST, BRADYCARDIA, ASYSTOLE, ARRHYTHMIAS AND HYPOTENSION HAVE ALSO BEEN REPORTED. THEREFORE, VITAL SIGNS MUST BE MONITORED CONTINUOUSLY.
General: The initial dose of ALFENTA (alfentanil hydrochloride) should be appropriately reduced in elderly and debilitated patients. The effect of the initial dose should be considered in determining supplemental doses. In obese patients (more than 20% above ideal total body weight), the dosage of ALFENTA should be determined on the basis of lean body weight. In one clinical trial, the dose of ALFENTA required to produce anesthesia, as determined by appearance of delta waves in EEG, was 40% lower in geriatric patients than that needed in healthy young patients. In patients with compromised liver function and in geriatric patients, the plasma clearance of ALFENTA may be reduced and postoperative recovery may be prolonged. Induction doses of ALFENTA should be administered slowly (over three minutes). Administration may produce loss of vascular tone and hypotension. Consideration should be given to fluid replacement prior to induction. Diazepam administered immediately prior to or in conjunction with high doses of ALFENTA may produce vasodilation, hypotension and result in delayed recovery. Bradycardia produced by ALFENTA may be treated with atropine. Severe bradycardia and asystole have been successfully treated with atropine and conventional resuscitative methods. The hemodynamic effects of a particular muscle relaxant and the degree of skeletal muscle relaxation required should be considered in the selection of a neuromuscular blocking agent. Following an anesthetic induction dose of ALFENTA, requirements for volatile inhalation anesthetics or ALFENTA infusion are reduced by 30 to 50% for the first hour of maintenance. Administration of ALFENTA infusion should be discontinued at leas 10-15 minutes prior to the end of surgery. Respiratory depression caused by opioid analgesics can be reversed by opioid antagonists such as naloxone. Because the duration of respiratory depression produced by ALFENTA may last longer than the duration of the opioid antagonist action, appropriate surveillance should be maintained. As with all potent opioids, profound analgesia is accompanied by respiratory depression and diminished sensitivity to CO_2 stimulation which may persist into or recur in the postoperative period. Intraoperative hyperventilation may further alter postoperative response to CO_2. Appropriate postoperative monitoring should be employed, particularly after infusions and large doses of ALFENTA, to ensure that adequate spontaneous breathing is established and maintained in the absence of stimulation prior to discharging the patient from the recovery area.
Head Injuries: ALFENTA may obscure the clinical course of patients with head injuries.
Impaired Respiration: ALFENTA should be used with caution in patients with pulmonary disease, decreased respiratory reserve or potentially compromised respiration. In such patients, opioids may additionally decrease respiratory drive and increase airway resistance. During anesthesia, this can be managed by assisted or controlled respiration.
Impaired Hepatic or Renal Function: In patients with liver or kidney dysfunction, ALFENTA should be administered with caution due to the importance of these organs in the metabolism and excretion of ALFENTA.
Drug Interactions: Both the magnitude and duration of central nervous system and cardiovascular effects may be enhanced when ALFENTA is administered in combination with other CNS depressants such as barbiturates, tranquilizers, opioids, or inhalation general anesthetics. Postoperative respiratory depression may be enhanced or prolonged by these agents. In such cases of combined treatment, the dose of one or both agents should be reduced. Limited clinical experience indicates that requirements for volatile inhalation anesthetics are reduced by 30 to 50% for the first sixty (60) minutes following ALFENTA induction. The concomitant use of erythromycin with ALFENTA can significantly inhibit ALFENTA clearance and may increase the risk of prolonged or delayed respiratory depression. Perioperative administration of drugs affecting hepatic blood flow or enzyme function may reduce plasma clearance and prolong recovery.
Carcinogenesis, Mutagenesis and Impairment of Fertility: No long-term animal studies of ALFENTA have been performed to evaluate carcinogenic potential. The micronucleus test in female rats and the dominant lethal test in female and male mice revealed that single intravenous doses of ALFENTA as high as 20 mg/kg (approximately 40 times the upper human dose) produced no structural chromosome mutations or induction of dominant lethal mutations. The Ames *Salmonella typhimurium* metabolic activating test also revealed no mutagenic activity.
Pregnancy Category C: ALFENTA has been shown to have an embryocidal effect in rats and rabbits when given in doses 2.5 times the upper human dose for a period of 10 days to over 30 days. These effects could have been due to maternal toxicity (decreased food consumption with increased mortality) following prolonged administration of the drug. No evidence of teratogenic effects has been observed after administration of ALFENTA in rats or rabbits. There are no adequate and well-controlled studies in pregnant women. ALFENTA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Labor and Delivery: There are insufficient data to support the use of ALFENTA in labor and delivery. Placental transfer of the drug has been reported; therefore, use in labor and delivery is not recommended.
Nursing Mothers: In one study of nine women undergoing post-partum tubal ligation, significant levels of ALFENTA were detected in colostrum four hours after administration of 60 μg/kg of ALFENTA, with no detectable levels present after 28 hours. Caution should be exercised when ALFENTA is administered to a nursing woman.
Pediatric Use: Adequate data to support the use of ALFENTA in children under 12 years of age are not presently available.
ADVERSE REACTIONS: The most common adverse reactions, respiratory depression and skeletal muscle rigidity, are extensions of known pharmacological effects of opioids. See CLINICAL PHARMACOLOGY, WARNINGS and PRECAUTIONS on the management of respiratory depression and skeletal muscle rigidity. Delayed respiratory depression, respiratory arrest, bradycardia, asystole, arrhythmias and hypotension have also been reported. The reported incidences of adverse reactions listed in the following table are derived from controlled and open clinical trials involving 1183 patients, of whom 785 received ALFENTA. The controlled trials involved treatment comparisons with fentanyl, thiopental sodium, enflurane, saline placebo and halothane. Incidences are based on disturbing and nondisturbing adverse reactions reported. The comparative incidence of certain side effects is influenced by the type of use, e.g., chest wall rigidity has a higher reported incidence in clinical trials of alfentanil induction, and by the type of surgery, e.g., nausea and vomiting have a higher incidence in patients undergoing gynecologic surgery.

Percent	ALFENTA (N=785)	Fentanyl (N=243)	Thiopental Sodium (N=66)	Enflurane (N=55)	Halothane (N=18)	Saline Placebo* (N=18)
Gastrointestinal						
Nausea	28	44	14	5	0	22
Vomiting	18	31	11	9	13	17
Cardiovascular						
Bradycardia	14	7	8	0	0	0
Tachycardia	12	12	39	36	31	11
Hypotension	10	8	7	7	0	0
Hypertension	18	13	30	20	6	0
Arrhythmia	2	2	5	4	6	0
Musculoskeletal						
Chest Wall Rigidity	17	12	0	0	0	0
Skeletal Muscle Movements	6	2	6	2	0	0
Respiratory						
Apnea	7	0	0	0	0	0
Postoperative Respiratory Depression	2	2	0	0	0	0
CNS						
Dizziness	3	5	0	0	0	0
Sleepiness/ Postoperative Sedation	2	8	2	0	0	6
Blurred Vision	2	2	0	0	0	0

*From two clinical trials, one involving supplemented balanced barbiturate/nitrous oxide anesthesia and one in healthy volunteers who did not undergo surgery.

In addition, other adverse reactions less frequently reported (1% or less) were: Laryngospasm, bronchospasm, postoperative confusion, headache, shivering, postoperative euphoria, hypercarbia, pain on injection, urticaria, and itching. Some degree of skeletal muscle rigidity should be expected with induction doses of ALFENTA.
DRUG ABUSE AND DEPENDENCE: ALFENTA (alfentanil hydrochloride) is a Schedule II controlled drug substance that can produce drug dependence of the morphine type and therefore has the potential for being abused.
OVERDOSAGE: Overdosage would be manifested by extension of the pharmacological actions of ALFENTA (alfentanil hydrochloride) (see CLINICAL PHARMACOLOGY) as with other potent opioid analgesics. No experience of overdosage with ALFENTA was reported during clinical trials. The intravenous LD_{50} of ALFENTA is 43.0-50.9 mg/kg in rats, 72.2-73.6 mg/kg in mice, 71.8-81.9 mg/kg in guinea pigs and 59.5-87.5 mg/kg in dogs. Intravenous administration of an opioid antagonist such as naloxone should be employed as a specific antidote to manage respiratory depression. The duration of respiratory depression following overdosage with ALFENTA may be longer than the duration of action of the opioid antagonist. Administration of an opioid antagonist should not preclude immediate establishment of a patent airway, administration of oxygen, and assisted or controlled ventilation as indicated for hypoventilation or apnea. If respiratory depression is associated with muscular rigidity, a neuromuscular blocking agent may be required to facilitate assisted or controlled ventilation. Intravenous fluids and vasoactive agents may be required to manage hemodynamic instability.
DOSAGE AND ADMINISTRATION: The dosage of ALFENTA (alfentanil hydrochloride) should be individualized in each patient according to body weight, physical status, underlying pathological condition, use of other drugs, and type and duration of surgical procedure and anesthesia. In obese patients (more than 20% above ideal total body weight), the dosage of ALFENTA should be determined on the basis of lean body weight. The dose of ALFENTA should be reduced in elderly or debilitated patients (see PRECAUTIONS). Vital signs should be monitored routinely. Protect from light. Store at room temperature 15°-30° C (59°-86° F).

Desflurane: First New Volatile Anesthetic in Almost 20 Years

John H. Tinker, MD

Department of Anesthesia, University of Iowa, Iowa City, Iowa

The halogenated volatile anesthetics, starting with fluroxene in 1952, with the major advance to halothane in 1956, and then methoxyflurane, enflurane, and isoflurane, have dramatically affected anesthetic practice. Pioneers in this arena including Suckling, Raventos, Johnstone (halothane); Larsen, Artusio, Van Poznak (methoxyflurane); Terrell and Eger (enflurane and isoflurane); Van Dyke and Brown (metabolism and toxicity); Robbins and Eger again (potency); Halsey and Miller (mechanisms) formed an important part of our heritage. Isoflurane, the most recently introduced halogenated volatile anesthetic, was really "ready-to-go" in 1974, but was sidetracked until 1981 by an ill-founded contention that it produced tumors in mice (*lots* of things produce tumors in mice). Most lay people, even most physicians for that matter, have little if any idea just how widely used these drugs are. We do about 27 million anesthetics yearly in the United States alone, of which about 23 million are general anesthetics. Halogenated volatile anesthetics are used in at least *two-thirds* of these. Worldwide, halothane use is still widespread; enflurane is also widely used in Europe, Japan, and Australia; more recently, isoflurane has been introduced in many countries.

As more and more surgery is performed on outpatients, the obvious need exists for anesthesia from which patients can recover rapidly, retain analgesia, be able to perform various self-care activities at home, and hopefully not suffer troublesome nausea and vomiting. Volatile agents have always been critical parts of our training and experience. Even though the "toxic therapeutic ratios" of the agents we use are quite low, implying danger, we are comforted by the relative ease with which we can usually "get it back" if we give too much, and the elegantly simple process of giving such agents by inhalation (now that we have accurate and reliable vaporizers).

On television, the "bad guy" places a handkerchief soaked in some mysterious fluid over a "victim's" face and the victim collapses in a heap in seconds. All of us, faced with various difficult clinical situations, have wished for a safe agent that would induce anesthesia just this fast. In the movies, the hero, badly shot up and operated on all night, comes to perfect alertness just as the heroine enters his (non-intensive care) room. Right.

From the real world, now, comes desflurane. Based on its blood-gas solubility of 0.41, a single-breath induction (perhaps not with a handkerchief) is at least theoretically possible. Changes in anesthetic depth or level are sufficiently fast that experienced anesthesiologists who have used desflurane say things like "its like driving a sports car—you get a constant feel for the patient," and "you feel like you're in better control as stimulus levels change." Our common current practice of discontinuing the volatile agent well before the end of surgery tends to deprive the patient of the agent's muscle relaxant properties. We then must rely on nitrous oxide (which is not a relaxant!) to finish the closure. This practice now conceivably could be modified. Desflurane's relaxant properties could be used almost to the last suture (staple?). The nitrous oxide could be discontinued first. Or perhaps we won't really need nitrous oxide at all with this agent? These possibilities are discussed in this Colloquium.
